ABSTRACT

This is a description of research in developing a natural language processing system with modular knowledge sources but strongly interactive processing. The system offers insights into a variety of linguistic phenomena and allows easy testing of a variety of hypotheses. Language interpretation takes place on a activation network which is dynamically created from input, recent context, and long-term knowledge. Initially ambiguous and unstable, the network settles on a single interpretation, using a parallel, analog relaxation process. We also describe a parallel model for the representation of context and priming of concepts. Examples illustrating contextual influence on meaning interpretation and "semantic garden path" sentence processing are included.

I INTRODUCTION

The interpretation of natural language requires the cooperative application of many kinds of knowledge, both language specific knowledge about word use, word order and phrase structure, and "real-world" knowledge about stereotypical situations, events, roles, contexts, and so on. And even though these knowledge systems are nearly decomposable, enabling the circumscription of individual knowledge areas for scrutiny, this decomposability does not easily extend into the realm of computation; that is, one cannot construct a psychologically realistic natural language processor by merely conjoining various knowledge-specific processing modules serially or hierarchically.

We offer instead a model based on the integration of independent syntactic, semantic, lexical, contextual, and pragmatic knowledge sources via spreading activation and lateral inhibition links. Figure 1 shows part of the network that is activated when the sentence

(S1) John shot some bucks.

is encountered. Links with arrows are activating, while those with circles are inhibiting. Mutual inhibition links between two nodes allow only one of the nodes to remain active for any duration. (However, both nodes may be simultaneously inactive.) Mutual inhibition links are generally placed between nodes that represent mutually

incompatible interpretations, while mutual activation links join compatible ones. If the context in which this sentence occurs has included reference to "gambling," only the shaded nodes of Figure 1 (a) remain active after relaxation of the network. If, on the other hand, "hunting" has been primed, only the shaded nodes shown in Figure 1 (b) will remain active.

Notice that the "decision" made by the system integrates syntactic, semantic, and contextual knowledge: the fact that "some bucks" is a legal noun phrase is a factor in killing the readings of "bucks" as a verb; the fact that "hunting" is associated with both the "fire" meaning of "shot" and the "deer" meaning of "bucks" leads to the activation of the coalition of nodes shown in Figure 1 (b); and so on. At the same time, the knowledge is discrete, and easy to add or modify. In this model of processing, decisions are spread out over time, allowing various knowledge sources to be brought to bear on the elements of the interpretation process. This is a radical departure from cognitive models based on the decision procedures that happen to be convenient in conventional programming languages. Of course, we are using a conventional language for simulating the system, but we plan to implement a connection machine [1].

Our program operates by (1) constructing a graph with weighted nodes and links from a sentence, and (2) running an iterative operation which recomputes each node's **activation level** (i.e. its weight) based on a function of its current value and the inner product of its links and the activation levels of its neighbors. For these examples, we are primarily interested in the behavior of the network, and not in the program that dynamically constructs the network. The syntactic portions of the networks in this paper are constructed by a chart parser [2], while the semantic and contextual portions are permanently resident in memory. Initially all nodes are given zero weight, except for the nodes used to model context (e.g. "hunting" and "gambling"). Each activation link has a weight of .2 and each inhibition link has a weight of -.45. The iterative operation uses a proportional function to compute new weighting for nodes, similar to the one used by McClelland and Rumelhart [3] in their interactive activation model.

The net effect of the program is that, over several iterations, a coalition of well-connected nodes will dominate, while the less fortunate

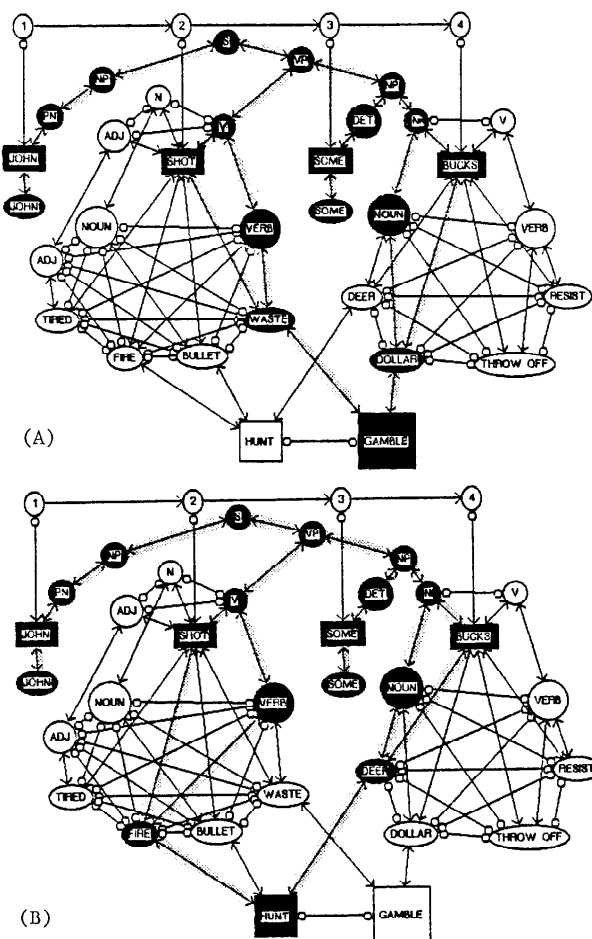

Figure 1: Two interpretations of "John shot some bucks." (A) Shows the result in the context of gambling, i.e. John wasted some money; (B) shows the result in the context of hunting, i.e. John fired a gun at a deer. Both examples required about 25 cycles to settle; in each case only a slight initial advantage was given to HUNT or GAMBLE. The numbered nodes control the arrival times of the words.

nodes (those which are negatively connected to winners) will be suppressed. We exploit this behavior several ways in our system: by putting inhibitory links between nodes which represent well-formed phrases with shared constituents (which are, thus, mutually exclusive), we ensure that only one will survive. Similarly, there are inhibitory links between nodes representing different lexical categories (i.e. noun or verb) for the same word; between concept nodes representing different senses of the same word (i.e. submarine as a boat or as a sandwich); and between nodes representing conflicting case role interpretations. There are activation links between phrases and their constituents, between words and their different meanings, between roles and their fillers, and between corresponding syntactic and semantic interpretations.

II MODELING PHENOMENOLOGY

Because our system operates in time, we are able to model effects that depend on context, and effects that depend on the arrival times of words. Consider the network shown in Figure 2, which shows three snapshots taken during the processing of the sentence (due to Charniak [4]):

(S2) The astronomer married a star.

Figure 2 includes three possible meanings for "star", namely (1) the featured player in dramatic acting, or (2) a celestial body, or 3) a pentagram. We presume that "astronomer" primes CELESTIAL-BODY by the path of strong links: astronomer → ASTRONOMER → ASTRONOMY → CELESTIAL-BODY, but that MOVIE-STAR would be primed very little, if at all, because any activation of HUMAN via "astronomer" and "married" is spread fairly evenly among a vast number of other concepts (PHYSICIAN, PROFESSOR, etc.). When the word "star" is encountered, the meaning CELESTIAL-BODY is initially highly preferred, but eventually, since CELESTIAL-BODY is inanimate, whereas the object of MARRY should be human and animate, the MOVIE-STAR meaning of "star" wins out.

In Figure 2(d) we show the activation levels for CELESTIAL-BODY and MOVIE-STAR as functions of time. The activation of CELESTIAL-BODY is initially very high; only later does MOVIE-STAR catch up to and eventually dominate it. We argue that, if activation level is taken as a prime determinant of the contents of consciousness, then this model captures a common experience of people when hearing this sentence. This phenomenon is often reported as being humorous, and could be considered a kind of "semantic garden path". It should be emphasized that this behavior falls out of this model, and is not the result of juggling the weights until it works. In fact, the examples shown in this paper work in an essentially similar way over a broad range of link weightings.

III CONTEXT: INTRODUCTION

Earlier (Figure 1) we used "context-setting" nodes such as "hunting" and "gambling" to prime particular word and phrase senses, in order to force appropriate interpretations of a noun phrase. There are, however, major problems that preclude the use of such context setting nodes as a solution to the problem of context-directed interpretation of language. A particular context-setting word, e.g. "hunting", may never have been explicitly mentioned earlier in the text or discourse, but may nonetheless be easily inferred by a reader or hearer. For example, preceding (S1) with:

(S3) John spent his weekend in the woods.

should suffice to induce the "hunting" context. Mention of such words or items as "outdoors", "hike", "campfire", "duck blind", "marksman", etc. ought to also prime a hearer appropriately, even though some of these words (e.g. "outdoors" and "hike") are more closely related to many other

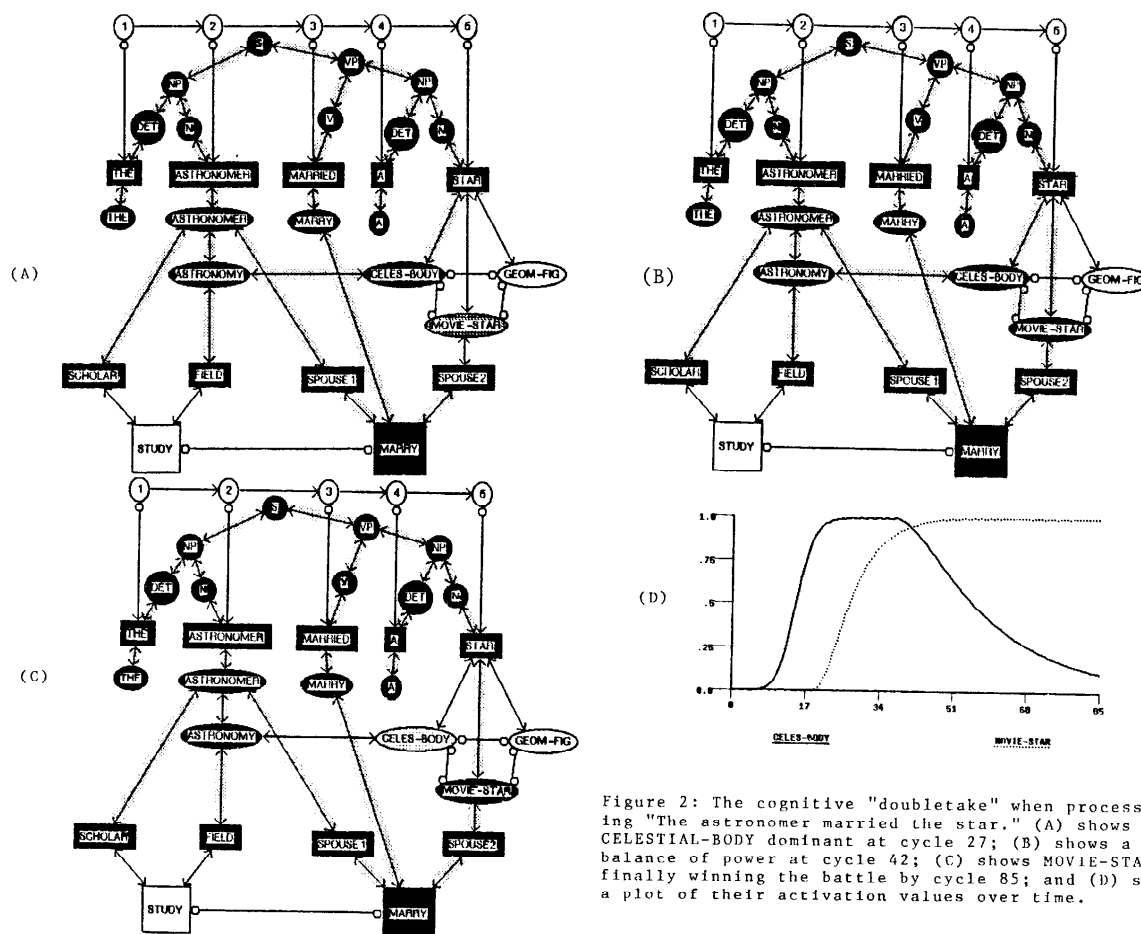

Figure 2: The cognitive "doubletake" when processing "The astronomer married the star." (A) shows CELESTIAL-BODY dominant at cycle 27; (B) shows a balance of power at cycle 42; (C) shows MOVIE-STAR finally winning the battle by cycle 85; and (D) shows a plot of their activation values over time.

concepts than to "hunting." We are thus apparently faced with either (a) the need to infer the special context-setting concept "hunting", given any of the words or items above; or (b) the need to provide connections between each of the words or items and all the various word senses they prime. There is, however, a better alternative.

We propose that each concept should be represented not merely as a unitary node, but should in addition be associated with a set of "microfeatures" that serve both (a) to define the concepts, at least partially, and (b) to associate the concept with others that share its microfeatures. We propose a large set of microfeatures (on the order of thousands), each of which is potentially connected to every concept node in the system (potentially on the order of hundreds of thousands). Each concept is in fact connected to only some subset of the total set, via either bidirectional activation or bidirectional inhibition links. Closely related concepts have many microfeatures in common.

We suggest that microfeatures should be chosen on the basis of first principles to correspond to the major distinctions humans make about situations in the world, that is, distinctions we must make to survive and thrive. For

example, some important microfeatures correspond to distinctions such as threatening/safe, animate/inanimate, edible/inedible, indoors/outdoors, good outcome/neutral outcome/bad outcome, moving/still, intentional/unintentional, or characteristic lengths of events (e.g., whether events require milliseconds, hours, or years). As in Hinton's [5] model, hierarchies arise naturally, based on subsets of shared microfeatures, but are not the fundamental basis for organizing concepts in a semantic network, as in most AI models.

A. Microfeatures as a Priming Context - An Example

Let us see how microfeatures could help solve the problems presented by the example in Figure 1. Figure 3 shows a partial set of microfeatures, corresponding to temporal event length or location (setting) running horizontally. A small set of concepts relevant to our example is listed across the top. Solid circles denote strong connection of concepts to microfeatures, open circles, a weak connection, and crosses, a negative connection.

A simple scoring scheme allows "weekend" and "outdoors" to appropriately prime concepts related to "fire at" and "deer" relative to "waste money" and

Figure 3a.

"dollar," as well as the ability of "casino" or "video game" to induce an opposite priming effect, as shown in Figure 3(c). It is interesting to compare these effects with the effects of priming with "hunting" or "gambling" directly. No relaxation was used, though it obviously could be (i.e. a concept could activate microfeatures, priming other concepts, and then the primed concepts could change the activation of the microfeatures, in turn activating new concepts and eventually settling down. We have been experimenting with a number of possible weighting and propagation schemes, and have built up a much larger matrix than the one shown in Figure 3.

IV RELATED WORK

There are many research projects which are very much in the same spirit as ours in addition to ones mentioned already in this paper. Beginning in the early 1970's, Schank argued that semantics, not syntax, should have the central role in both theories and programs for natural language processing; Riesbeck's parser for MARGIE [6] has a clear relationship to the model proposed here. Small [7] was another worker in AI to question the traditional serial integration of

PRIMING CONCEPTS	PRIMED CONCEPTS			
	Fire-at	Waste	Deer	Dollar
Weekend	.41	.55	0	.46
Outdoors	.41	0	.44	.08
Casino	.05	.59	0	.42
Video Games	.18	.36	0	.19
Weekend + Outdoors	.41	.07	.25	.12
Hunting	.36	0	.50	0
Gambling	.09	.59	0	.38

Fraction of Maximum Possible Score

Figure 3b: Instantaneous priming effects on concepts; microfeatures start at 0, and undergo a single priming cycle.

Figure 3: This figure illustrates the use of microfeatures to provide contextual priming. At any given time, microfeatures will display some pattern of activation. Each concept has an induced activation level as a result of the microfeature activation values. The microfeature activations are modified whenever a concept is primed. For our example, assume "weekend" is primed, with all microfeatures initially at 0. The top line of Figure 3b shows the activation levels of concepts, where the number represents a fraction of the maximum possible activation for that concept. These values prime various word sense nodes differently.

language processing. He suggested that rather than having separate modules for syntax and semantics, each word was an expert in interpreting its own meaning and role in context. Following on that work, Cottrell is re-casting word-sense selection into a connectionist framework, and his work is very closely related to our own [8]. Jones [9] is also working on parsing with spreading activation, but of the digital kind.

Other work has set integrated parsing into the production system framework. BORIS [10] uses a lexically-based demon-driven production system to read stories and answer questions about them. The READER system [11] is a multi-level parallel production system which models chronometric data, i.e. data on how long humans visually fixate on each word while reading.

Another interesting approach to language integration is taken by Hendler and Phillips [12], who are using a message-passing ACTOR [13] system to model the interactions between syntax, semantics and pragmatics. Other work that has influenced our research includes the spreading activation work by Ortony and Radin [14], based on a network of free associations to English words.

V CONCLUSION

Using spreading activation and lateral inhibition enables a good framework for embedding comprehension phenomena which cannot even be approached with binary serial models. While we have not discussed them here, we have explored ties to psychological and linguistic results and theories; these are reported in Waltz and Pollack [15]. There we show that structural preferences such as Minimal Attachment [16] can be understood as side-effects of, rather than as strategies for, a syntactic processor; current hypotheses about lexical disambiguation in context [17,18] can nicely fit into a model with lateral inhibition, but cannot be accounted for by activation alone. Garden-paths at different levels of processing can be explained by the breakdown of a common approximate consistent labeling algorithm -- Lateral Inhibition -- the "Universal Will to Disambiguate."
