Abstract
Possibilistic networks are belief graphical models based on possibility theory. A possibilistic network either represents experts’ epistemic uncertainty or models uncertainty from poor, scarce or imprecise data. Learning possibilistic networks from data in general and from imperfect or scarce datasets in particular, has not received enough attention. This work focuses on parameter learning of possibilistic networks. The main contributions of the paper are i) a study of an extension of the information affinity measure to assess the similarity of possibilistic networks and ii) a comparative empirical evaluation of two approaches for learning the parameters of a possibilistic network from empirical data.

Introduction
Belief graphical models are compact and powerful representations of uncertain information. Examples of such models are Bayesians networks, credal networks (Cozman 2000) and possibilistic ones (Borgelt and Kruse 2003). Belief networks are either built from information elicited directly from experts or learnt automatically by machine learning techniques from empirical data. Possibilistic formalisms are more suitable for representing qualitative and incomplete information. However, there are only few works dealing with learning possibilistic networks from data (Kruse and Borgelt 1995; Haddad, Leray, and Amor 2015). In particular, learning a possibilistic network may be case in point of small datasets or datasets with missing or imprecise information (Dubois and Prade 2016).

Learning a graphical belief model comes down in general to i) learn the graphical component, also called structure (namely, extract and encode the independence relationships) and ii) learn the parameters (fill the local tables) associated with each variable. In this paper, we focus on parameter learning of possibilistic networks. Namely, given a structure and a dataset, the goal is to assess local possibility tables of each variable in the context of its parents. The main contributions of the paper are:

- An empirical comparison of two main approaches for learning possibility distributions from data on synthetic datasets. This evaluation compares the networks learnt using two different approaches using a generalized form of the information affinity measure.
- An empirical comparison of learning naive possibilistic network classifiers from real datasets. The evaluation here aims to compare the predictive power of possibilistic classifiers learnt from small datasets containing missing data.

Possibilistic networks
Bayesian networks allow to compactly encode a probability distribution thanks to the conditional independence relationships existing between the variables. Credal networks (Cozman 2000), based on the theory of credal sets, generalize Bayesian networks in order to allow some flexibility regarding the model parameters. They are for instance used in robustness analysis and for encoding incomplete and ill-known knowledge and reasoning with the knowledge of groups of experts. Possibilistic networks are the counterparts of Bayesian networks based on possibility theory (Dubois and Prade 1988), more suited for handling imperfect, qualitative and partial information.

Possibilistic networks
A possibilistic network \( PN = <G, \Theta> \) is specified by:

i) A graphical component \( G \) consisting of a directed acyclic graph (DAG) where vertices represent the variables and edges represent direct dependence relationships between variables. Each variable \( A_i \) is associated with a domain \( D_{A_i} \) containing the values \( a_1 \) taken by a variable \( A_i \).

ii) A numerical component \( \Theta \) allowing to weight the uncertainty relative to each variable using local possibility tables. The possibilistic component consists in a set of local possibility tables \( \theta_i = \pi(A_i | \text{par}(A_i)) \) for each variable \( A_i \) in the context of its parents \( \text{par}(A_i) \) in the network \( PN \).

Note that all the local possibility distributions \( \theta_i \) must be normalized, namely \( \forall i = 1..n \), for each parent context \( \text{par}(a_i) \), \( \max_{a_i \in D_i} (\pi(a_i | \text{par}(a_i)) = 1 \).

Example 1. Fig. 1 gives an example of a possibilistic network over four Boolean variables \( A, B, C \) and \( D \). The structure of \( G \) encodes a set of independence relationships. For

Copyright © 2017, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.
example, variable C is independent of B and D in the context of A.

In the possibilistic setting, the joint possibility distribution is factorized using the following possibilistic counterpart of the chain rule:

\[
\pi(a_1, a_2, \ldots, a_n) = \bigotimes_{i=1}^{n} \pi(a_i | \text{par}(a_i)).
\]  

(1)

where \( \otimes \) denotes the product or the min-based operator depending on the quantitative or the qualitative interpretation of the possibilistic scale (Dubois and Prade 1988). In this work, we are interested only in product-based possibilistic networks since we view possibility degrees as upper bounds of probability degrees.

Learning the parameters of a possibilistic network

Learning the parameters of a possibilistic network is the problem of assessing the entries of local possibility tables \( \pi(A_i | \text{par}(A_i)) \) for each variable \( A_i \) given a structure \( S \) and a dataset \( D \). The structure here is assumed to be given (e.g. when learning naive classifiers, the structure is fixed in advance by assumption) or learnt automatically. There are basically two ways to learn the parameters (Haddad, Leray, and Amor 2015): i) Transformation-based approach (TA for short) and ii) Possibilistic-based approach (PA for short). Note that the authors in (Serrurier and Prade 2015) propose a possibilistic-based method for learning the structure of a Bayesian network.

Transformation-based approach

This approach consists in first learning the parameters of a probabilistic network then transforming the obtained probabilistic network into a possibilistic one (Haddad, Leray, and Amor 2015; Benferhat, Levray, and Tabia 2015a; Slimen, Ayuchi, and Amor 2013).

Many probability-possibility transformations exist (Dubois, Prade, and Sandri 1993). Among these transformations, the optimal transformation \( (OT) \) (Dubois et al. 2004) is defined as follows:

\[
\pi_1 = \sum_{i/j \leq p_i} p_j,
\]  

(2)

where \( \pi_i \) (resp. \( p_i \)) denotes \( \pi(\omega_i) \) (resp. \( p(\omega_i) \)). The transformation of Equation 2 transforms \( p \) into \( \pi \) and guarantees that the obtained possibility distribution \( \pi \) is the most specific1 (hence most informative) one that is consistent and preserving the order of interpretations.

In case where the probabilistic model is a credal one, one can make use of imprecise probability - possibility transformations turning for instance an interval-based probability distribution (IPD) into a possibilistic one. For instance, the transformation proposed in (Masson and Denoeux 2006) allows to find a possibility distribution dominating all the probability measures defined by probability intervals. This transformation tries on the one hand to preserve the order of interpretations induced by the IPD and the dominance principle requiring that \( \forall \phi \subseteq \Omega, P(\phi) \leq \Pi(\phi) \) on the other hand. Such transformations correspond to viewing possibility degrees as upper bounds of probability degrees (Dubois, Prade, and Sandri 1993). In (Destercke, Dubois, and Chojnacki 2007), the authors claim that any upper generalized \( R \)-cumulative distribution \( F \) built from one linear extension can be viewed as a possibility distribution and it also dominates all the probability distributions that are compatible with the IPD. Let \( C_i \) be a linear extension compatible with the partial order \( M \) induced by an IPD. Let \( \phi_1, \phi_2, \ldots, \phi_n \) be subsets of \( \Omega \) such that \( \phi_i = \{ \omega_j | \omega_j \leq c_i \} \). The upper cumulative distribution \( F \) built from one linear extension \( C_i \) is as follows (see (Destercke, Dubois, and Chojnacki 2007) for more details):

\[
F(\phi_i) = \min( \sum_{\omega_j \in \phi_1} u_j, 1 - \sum_{\omega_j \notin \phi_1} l_j )
\]  

(3)

The obtained cumulative distribution \( F \) is a possibility distribution dominating the IPD and it is such that \( F(\phi_i) = \Pi(A_i) \). The advantage of such a transformation, also called \( p \)-box transformation, is its low computational cost (linear in the size of domains) and the fact that the obtained distribution is better in terms of specificity (meaning that the transformation process losses less information).

Possibilistic-based approach

One view of possibility theory is to consider a possibility distribution \( \pi \) on a variable \( A_i \) as a contour function of a random set (Shafer and others 1976) pertaining to \( D_i \), the domain of \( A_i \). A random set in \( D_i \) is a random variable which takes its values on subsets of \( D_i \). More formally, let \( D_i \) be a finite domain. A basic possibility assignment or mass function is a mapping \( m : 2^{D_i} \rightarrow [0, 1] \) such that \( \sum_{a_i \subseteq D_i} (m(a_i)) = 1 \) and \( m(\emptyset) = 0 \). A set \( a_i \subseteq D_i \) such that \( m(a_i) > 0 \) is called a focal set.

The possibility degree of an event \( \omega_i \) is the probability of the possibility of the event i.e. the probability of the disjunction of all events (focal sets) \( a_i \) in which this event is included (Borgelt, Steinbrecher, and Kruse 2009):

\[
\pi(\omega_i) = \sum_{a_i | a_i \cap a_i' \neq \emptyset} m(a_i)
\]  

(4)

1Let \( \pi' \) and \( \pi'' \) be two possibility distributions, \( \pi' \) is more specific than \( \pi'' \) iff \( \forall \omega_i \in \Omega, \pi'(\omega_i) \leq \pi''(\omega_i) \).
A random set is said to be consistent if there is at least one element $a_i$ contained in all focal sets $a_i$, and the possibility distribution induced by a consistent random set is, thereby, normalized. Exploring this link between possibility theory and random sets theory has been extensively studied, in particular, in learning tasks, we cite for instance (Borgelt, Steinbrecher, and Kruse 2009; Joslyn 1997). In what follows, we present obtained results i.e. the possibilistic-likelihood-based parameters algorithm.

Given a DAG and an imprecision degree $S_i$, let $D_{ij} = \{d^{(l)}_{ij}\}$ be a dataset relative to a variable $A_i$, $d^{(l)}_{ij} \in D_{ij}$ (resp. $d^{(l)}_{ij} \subseteq D_{ij}$) if data are precise (resp. imprecise). The number of occurrences $A_i = a_{ik}$ such that $Pa(A_i) = j$, denoted by $N_{ij,k}$, is the number of times $A_i = a_{ik}$ such that $Pa(A_i) = j$ appears in $D_{ij}$: $N_{ij,k} = \text{card}(\{1 \text{ s.t. } A_i = a_{ik} \text{ s.t. } Pa(A_i) = j \in d^{(l)}_{ij}\})$.

\[ \pi(A = a_{ik} | Pa(A_i) = j) = \frac{N_{ij,k}}{\sum_{i=1}^{r_i} N_{ij,k} * S_i} \quad (5) \]

where $q_i = \text{card}(Pa(X_i))$, $r_i=\text{card}(D_{ij})$ and $S_i$ corresponds to the imprecision degree relative to a variable $A_i$. To obtain normalized possibility distributions, we divide each obtained distribution by its maximum. It is evident that this operation eliminates $S_i$. However, we could assign to each value of $X_i$ an imprecision degree which could be either set by an expert or inferred from the dataset to learn from.

**Comparing approaches for learning parameters of possibilistic networks**

When learning belief graphical models, the evaluation is generally done by comparing reference networks with the learnt ones. Reference networks are graphical models that are either chosen by an expert or randomly generated. From the reference model, a dataset is generated following the distribution encoded by the reference model. This dataset is then used to learn models using the approach to be evaluated. The problem then comes down to compare the learnt model with the reference one. A comparison may take into account only the joint measures encoded by the learnt and the reference models. In addition, one may want also to take into account the structure of the learnt and reference models. Given that we are only interested in comparing possibilistic networks with same structure, there is no need to consider the graphical component in our comparisons. One simple but costly way of comparing the reference network with the learnt one is to compare only the joint distribution encoded by the reference model with the learnt model distribution. An example of similarity measure for possibility distributions is information affinity (Jenhani et al. 2007). However the size of the distribution may be very huge (it fact, it is exponential in the number of variables of the network) making it impossible to compare joint possibility distributions. We propose a heuristic method that compares the networks local distributions locally and aggregates the results to provide an overall similarity score of two possibilistic networks.

**Similarity of two possibilistic networks**

Many measures were proposed for assessing the similarity between two possibility distributions $\pi_1$ and $\pi_2$ over the same universe of discourse $\Omega$. Among such measures, information affinity (Jenhani et al. 2007), is defined as follows:

\[ \text{InfoAff}(\pi_1, \pi_2) = 1 - \frac{d(\pi_1, \pi_2) + \text{Inc}(\pi_1, \pi_2)}{2} \]

where $d(\pi_1, \pi_2)$ represents the mean Manhattan distance between possibility distributions $\pi_1$ and $\pi_2$ and it is defined as follows: $d(\pi_1, \pi_2) = \frac{1}{|\Omega|} \sum_{i=1}^{N} |\pi_1(\omega_i) - \pi_2(\omega_i)|$. As for $\text{Inc}(\pi_1, \pi_2)$, it is a measure of inconsistency and it assesses the conflict degree between $\pi_1$ and $\pi_2$. Namely, $\text{Inc}(\pi_1, \pi_2)=1-\max_{\omega_i \in \Omega}(\pi_1(\omega_i) \land \pi_2(\omega_i))$ where $\pi_1(\omega_i) \land \pi_2(\omega_i)$ denotes a combination operation of two possibility distributions. In (Jenhani et al. 2007) , the min operator is used in a qualitative setting. In a quantitative setting, a product operator can be used as well. The measure of Equation 6 satisfies the following natural properties:

- **(P1) Non-negativity**: $\text{InfoAff}(\pi_1, \pi_2) \geq 0$.
- **(P2) Symmetry**: $\text{InfoAff}(\pi_1, \pi_2) = \text{InfoAff}(\pi_2, \pi_1)$.
- **(P3) Upper bound and Non-degeneracy**: $\text{InfoAff}(\pi_1, \pi_2)$ is maximal iff $\pi_1$ and $\pi_2$ are identical. Namely, $\text{InfoAff}(\pi_1, \pi_2)=1$ iff $\forall \omega_i \in \Omega, \pi_1(\omega)=\pi_2(\omega)$.
- **(P4) Lower bound**: $\text{InfoAff}(\pi_1, \pi_2)$ is minimal iff $\pi_1$ and $\pi_2$ contain maximally contradictory possibility distributions. Namely, $\text{InfoAff}(\pi_1, \pi_2)=0$ iff
  - i) $\forall \omega_i \in \Omega, \pi_1(\omega) \in \{0, 1\}$ and $\pi_2(\omega) \in \{0, 1\}$, and
  - ii) $\pi_1(\omega)=1-\pi_2(\omega)$
- **(P5) Inclusion**: If $\pi_1$, $\pi_2$ and $\pi_3$ are three possibility distributions over the same universe of discourse $\Omega$ and $\forall \omega_i \in \Omega, \pi_1(\omega) \leq \pi_2(\omega) \leq \pi_3(\omega)$ then $\text{InfoAff}(\pi_1, \pi_2) \geq \text{InfoAff}(\pi_1, \pi_3)$.
- **(P6) Permutation**: This property states that permuting the degrees or indexes of possibility distributions should result in the same information affinity. Formally, $\text{InfoAff}(\pi_1, \pi_2)=\text{InfoAff}(\sigma(\pi_1), \sigma(\pi_2))$ where $\pi_1$, $\pi_2$ are two possibility distributions over $\Omega$ and $\sigma(\pi)$ is a permutation\(^3\) of elements of $\pi$.

**Similarity of two possibilistic networks**

To assess the similarity of two possibilistic networks $G_1$ and $G_2$ having the same structure (same DAG), it may be relevant to compare every local possibility distribution $\pi_1$ in the network $G_1$ with $\pi_2$, namely its corresponding distribution in $G_2$. This can be done for instance using an aggregation function that takes into account all the local distributions and returns a global similarity score between $G_1$ and $G_2$.

\[ \text{GrInfoAff}(G_1, G_2) = \text{Agg}_{i=1,n}(\text{InfoAff}(\pi_1^i, \pi_2^i)) \]

To the best of our knowledge, there is no decomposable similarity measure over possibilistic networks. As examples of aggregation functions, one can use the minimum,
maximum, mean, weighted mean, sum, product, etc. In order to study the properties of similarity measures of Equation 7, let us first rephrase properties P1-P6 in case where the possibility distributions \( \pi_1 \) and \( \pi_2 \) are compactly encoded by means of networks \( G_1 \) and \( G_2 \).

- (GP1) Non-negativity: \( \text{GrInfoAff}(G_1, G_2) \geq 0 \).
- (GP2) Symmetry: \( \text{GrInfoAff}(G_1, G_2) = \text{GrInfoAff}(G_2, G_1) \).
- (GP3) Upper bound and Non-degeneracy: \( \text{GrInfoAff}(G_1, G_2) \) is maximal iff the joint possibility distributions \( \pi_{G_1} \) and \( \pi_{G_2} \) encoded respectively by \( G_1 \) and \( G_2 \) are identical. Namely, \( \text{GrInfoAff}(G_1, G_2) = 1 \) iff \( \forall i=1..n, \forall a_i \in D_i, \pi_{G_1}(a_{1a_2..a_n}) = \pi_{G_2}(a_{1a_2..a_n}) \). This property only requires that the two joint possibility distributions encoded by \( G_1 \) and \( G_2 \) are identical to give a maximal similarity score.
- (GP4) Lower bound: \( \text{GrInfoAff}(G_1, G_2) \) is minimal iff the joint distributions \( \pi_{G_1} \) and \( \pi_{G_2} \) contain maximally contradictory possibility distributions. Namely, \( \text{GrInfoAff}(G_1, G_2) = 0 \) iff
  
  \[
  \pi_{G_1}(a_{1a_2..a_n}) \in \{0,1\} \quad \text{and} \quad \pi_{G_2}(a_{1a_2..a_n}) \in \{0,1\}, \quad \text{and} \\
  \pi_{G_1}(a_{1a_2..a_n}) = 1-\pi_{G_2}(a_{1a_2..a_n}),
  \]

- (GP5) Inclusion: If \( \pi_{G_1}, \pi_{G_2} \) and \( \pi_{G_3} \) are three possibility distributions encoded respectively by three possibilistic networks \( G_1, G_2 \) and \( G_3 \) such that \( \forall a_i \in D_i, \pi_{G_1}(a_{1a_2..a_n}) \leq \pi_{G_2}(a_{1a_2..a_n}) \leq \pi_{G_3}(a_{1a_2..a_n}) \) then \( \text{GrInfoAff}(G_1, G_2) \geq \text{GrInfoAff}(G_1, G_3) \).
- (GP6) Permutation: This property states that permuting the degrees or indexes of joint possibility distributions should result in the same \( \text{GrInfoAff} \). Formally, \( \text{GrInfoAff}(\pi_{G_1}, \pi_{G_2}) = \text{GrInfoAff}(\sigma(\pi_{G_1}), \sigma(\pi_{G_2})) \) where \( \sigma(\pi_{G_1}) \) is a permutation of the degrees or indexes of the joint possibility distribution \( \pi_{G_1} \).

The following proposition provides for each aggregation function among max, min, sum, mean and product the set of properties defined above that are satisfied by the affinity measure based on such an aggregation function.

**Proposition 1.** Let \( G_1 \) and \( G_2 \) be two possibilistic networks defined over the same set of variables \( V = \{A_1, ..., A_v\} \) and sharing the same DAG. Then \( \text{GrInfoAff} \) satisfies the properties given in Table 1 depending on the used aggregation function.

The proof is omitted due to space limitations. In our first series of experiments, we used the mean aggregation function since it satisfies most of the properties and it outputs a score taking into account all the local scores of local tables.

### Experimental studies

**Assessing the similarity of possibilistic networks**

**Experimentation setup** In this experiment, given a dataset \( D \) and a network structure (DAG) \( S \), we compare learning a possibilistic network parameters using two approaches, \( TA \) and \( PA \). We denote by \( G^{TA} \) (resp. \( G^{PA} \)) the possibilistic network having the structure \( S \) and its parameters are learnt over the dataset \( D \) using the transformation-based approach \( TA \) based on the p-box transformation (resp. the possibilistic-based approach \( PA \)).

We first generated a set of possibilistic networks with different features (number of variables, number of parents per variable, rate of imprecise data, etc.). For each possibilistic network \( G \), we generate datasets according to \( G \). More precisely, for each possibilistic network \( G \) (characterized by its number of variables denoted \# variables, the mean number of parents per node denoted \( \mu \) variables and the mean domain size of variables \( \mu \) domain), we generate many datasets (with different sizes). Regarding the dataset generation process, it consists in generating an imprecise dataset representative of its possibility distribution. The sampling process constructs a database of \( N \) (predefined) observations by instantiating all variables w.r.t. their possibility distributions using the \( \alpha \)-cut notion expressed as follows:

\[
\alpha - \text{cut}_{A_i} = \{a_i \in D_i \text{ s.t. } \pi(a_i) \geq \alpha\}
\]

(8)

where \( \alpha \) is randomly generated from \([0,1]\). Obviously, variables are mostly easily processed w.r.t. a topological order, since this ensures that all parents are instantiated. Instantiating a parentless variable corresponds to computing its \( \alpha \)-cut. Instantiating a conditioned variable \( A_i \) s.t. \( Pa(A_i) = A \) corresponds to computing the \( \alpha \)-cut of \( \pi(A_i | Pa(A_i) = A) \) computed as follows:

\[
\pi(A_i | Pa(A_i) = A) = \max_{a_i \in A} (\pi(A_i | a_i), \pi(a_i))
\]

(9)

Table 2 gives the details on the generated possibilistic networks and the corresponding datasets.

The results of Table 3 show that on the one hand the learnt possibilistic networks using the \( TA \) approach are close to the reference ones.

Namely, they have rather a good similarity with the reference possibilistic networks used to generate the datasets. Moreover, the obtained similarity scores do not seem to be affected by the number of variables, variable domains size, etc. Regarding the possibilistic networks learnt using the PA approach, their similarity scores are slightly better, but this is expected as the datasets generation process and the PA approach have the same view of possibility degrees. Such results also rise the issue of similarity measures on possibilistic networks which is still an open issue.

Predictive power of possibilistic classifiers

In this section, we evaluate the predictive power of credal network classifiers (Corani and Zaffalon 2008), naive Bayes classifiers and naive possibilistic classifiers (Benferhat and Tabia 2012). More precisely, we compare on many datasets the classification efficiency of naive credal classifier (NCC for short) and the corresponding possibilistic classifiers obtained either using the possibilistic-based approach (PNC\textsubscript{PA}) or using the transformation-based approach (PNC\textsubscript{TA}). Moreover, we compare our results to naive Bayes classifier (NBC) as a baseline.

Classification using belief graphical models is a special kind of inference: given an observation, it is required to determine the class label of the observed instance among a predefined set of class labels. In classification problems, one node represents the class variable \(C\), and the remaining nodes are attributes \(A_1, A_2, ..., A_n\) that may be observable. Given an observation denoted \((a_1, a_2, ..., a_n)\) of \(A\), the candidate class \(C\) is predicted by possibilistic classifiers as follows:

\[
C = \arg\max_{c_k} \Pi_c(c_k | a_1, a_2, ..., a_n),
\]

where the term \(\Pi_c(c_k | a_1, a_2, ..., a_n)\) denotes the conditional possibility degree of having \(c_k\) the actual class given the observation \(a_1, a_2, ..., a_n\).

A naive possibilistic (resp. Bayes) network classifier is a simple form of possibilistic (resp. Bayes) classifier. It assumes that attributes are independent in the context of the class node. Hence, the only dependencies allowed in naive networks are from the class node \(C\) to each attribute \(A_i\). Learning a naive classifier in our context comes down to learning the local tables (namely the table of \(C\) and a conditional table for of each \(A_i\) in the context of \(C\)) from data since the structure is fixed in advance.

Experimentation setup To evaluate the NCC classifier, we use measures used in (Corani and Zaffalon 2008):

- **Determinacy (Det)**: It is the percentage of predictions outputting a unique (precise) class label.
- **Single-Accuracy (SiAcc)**: It denotes the percentage of correct classifications when the predictions of NCC are precise.
- **Set-Accuracy (SetAcc)**: It is the proportion of imprecise predictions containing the right class label.

A 10-fold cross validation is used in this experiment.

Benchmarks The experimental study is carried out on the following datasets where some data values are missing (here, missing data is assumed to be not missing at random). The first four datasets of Table 4 are real datasets used in the literature for evaluating classifiers with missing data (3). The remaining ones are collected from different sources.

Table 6 gives the results of evaluating the NBC (Naive Bayes Classifier), PNC\textsubscript{TA} and PNC\textsubscript{PA} classifiers on the datasets of Table 4. Results of Table 6 show that classifiers NBC, PNC\textsubscript{PA} and PNC\textsubscript{TA} have most of the time comparable results in terms of correct classification rates on some datasets but they show real performances on some other datasets. This is also valid for the results of the NCC classifier. Typically, it’s on small datasets with many classes where the NCC is not efficient.

Table 6: Results of the $NBC$, $PNC_S$ and $PNC_T$ classifiers on the datasets of Table 4.

**Discussions and concluding remarks**

The main objective of this paper is comparing two methods for assessing the parameters of a possibilistic network given a structure and a dataset. To do this, we proposed to compare them against two criteria: the similarity of the obtained networks and the predictive power of the networks used as classifiers. In order to assess the similarity of two possibilistic networks, a generalization of the possibilistic affinity measure is analyzed with respect to the use of different aggregation functions. The first series of experiments in our comparison mainly shows that the possibilistic-based method learns slightly better and more information in terms of information affinity than the method based on the probability-possibility transformation. This is not really surprising since the data was generated according to the possibility distributions of the reference networks. This also confirms that there is inevitably some information loss when transforming probability distributions into possibilistic ones (Dubois et al. 2004; Benferhat, Levray, and Tabia 2015b). Regarding the second series of experiments, one important result is that the classifiers based on possibilistic networks have comparable efficiency with naive Bayes and credal classifiers. On the other hand, the possibilistic classifiers where the parameters have been learned with two different approaches have basically comparable results. Overall, these results show that there is no approach that clearly outperforms the others on all the datasets. Such results are preliminary but encouraging, a further comparative study on a large number of benchmarks and problems (classification and inference in general) using naive and non naive models, will be needed to really compare the two approaches. Moreover, we’ll be in particular interested in comparing these possibilistic approaches with EM approach used to estimate parameters from partially observed data in probabilistic models.
