Abstract

Demand-side management (DSM) in the smart grid allows customers to make autonomous decisions on their energy consumption, helping energy providers to reduce the peaks in load demand. The automated scheduling of smart devices in residential and commercial buildings plays a key role in DSM. Due to data privacy and user autonomy, such an approach is best implemented through distributed multi-agent systems. This paper makes the following contributions: (i) It introduces the Smart Home Device Scheduling (SHDS) problem, which formalizes the device scheduling and coordination problem across multiple smart homes as a multi-agent system; (ii) It describes a mapping of this problem to a distributed constraint optimization problem; (iii) It proposes a distributed algorithm for the SHDS problem; and (iv) It presents empirical results from a physically distributed system of Raspberry Pis, each capable of controlling smart devices through hardware interfaces.

Introduction

Demand-side management (DSM) in the smart grid allows customers to make autonomous decisions on their energy consumption, helping the energy providers to reduce the peaks in load demand. Typical approaches for DSM focus on enforcing grid users’ decisions to reduce consumptions by either (i) storing energy during off-peak hours and using the stored energy when the grid load demand is high, or (ii) scheduling shiftable loads in off-peak hours (Voice et al. 2011; Logenthiran, Srinivasan, and Shun 2012). The former approach requires that homeowners own storage devices, in the form of batteries or electric vehicles; these are still rare resources in the current, and near future, smart grid scenarios. The latter approach is more appealing for the current smart grid scenario, but requires producers to control a portion of the consumers electrical appliances, which strongly affects privacy and users’ autonomy.

On the other hand, residential and commercial buildings are progressively being partially automated, through the introduction of smart devices (e.g., smart thermostats, circulator heating, washing machines). In addition, a variety of smart plugs, that allow users to intelligently control devices by remotely switching them on and off, are now commercially available. Device scheduling can, therefore, be executed by users, without the control of a centralized authority. However, uncoordinated scheduling may be detrimental to DSM performance without reducing peak load demands (Van Den Briel et al. 2013). For an effective DSM, a coordinated device scheduling within a neighborhood of buildings is necessary. Yet, privacy concerns arise when users share resources or cooperate to find suitable schedules.

In this paper, we provide the following contributions: (i) We introduce the Smart Home Device Scheduling (SHDS) problem, which formalizes the problem of coordinating smart devices schedules across multiple smart homes as a multi-agent system; (ii) We propose a mapping of the SHDS problem as a distributed constraint optimization problem, when the agents are assumed to be cooperative; (iii) We show how to solve this problem in a distributed manner; and (iv) We evaluate this distributed algorithm on a physically distributed system of Raspberry Pis, each capable of controlling a number of smart devices through hardware interfaces, such as Z-Wave dongles.

Background and Related Work

The problem of scheduling devices in smart homes has recently attracted large interest within the AI and smart grid communities. Georgievski et al. (2012) proposed a system to monitor and control electrical appliances in a home with the objective of reducing the energy consumption costs. Scott et al. (2013) also studied a centralized online stochastic optimization approach for (single) home automation systems as a DSM mechanism, where future prices, occupant behavior, and environmental conditions are uncertain. Sou et al. (2011) proposed a Mixed Integer Linear Program (MILP) to address smart appliance scheduling problem in single homes using a fine granularity for the technical specification of smart appliance (e.g., they distinguish the different energy phases expressed by a dishwasher or a washing machine cycle). Due to the high complexity of the problem, the authors suggest to adopt suboptimal solutions to reduce the overall resolution time. Another proposal to enhance the resolution time of a MILP formulation for scheduling smart devices has been presented by Tsui and Chan (2012), through a MILP convex relaxation for the automatic load management of appliances in a smart home. Such an approach, however, pro-
vides no guarantees on the solution quality with respect to the original problem. Unlike our approach, these proposals focus on single-home problems and/or are inherently centralized. In contrast, we focus on a distributed approach applied to multiple homes.

Researchers have also used distributed constraint optimization problem (DCOP) algorithms to solve resource allocation problems in the smart grid. For example, DCOP solutions to electric vehicle charging problems have been proposed in (Lutati et al. 2014). Differently from such approaches, in our proposal we use a DCOP framework to solve a distributed scheduling problem for smart devices in smart homes. Similar to those approaches, we too propose to use the DCOP framework for our problem, but our underlying scheduling problem is different—we are scheduling smart devices in homes instead of electric vehicles in charging stations.

Scheduling of Devices in Smart Homes

A Smart Home Devices Scheduling (SHDS) problem is defined by the tuple \(\langle H, Z, L, P_H, P_Z, H, \theta \rangle\), where:

- \(H = \{h_1, h_2, \ldots\}\) is a neighborhood of smart homes, capable of communicating with one another,
- \(Z = \cup_{h_i \in H} Z_i\) is a set of smart devices, where \(Z_i\) is the set of devices in the smart home \(h_i\) (e.g., vacuum cleaning robot, smart thermostat),
- \(L = \cup_{h_i \in H} L_i\) is a set of locations, where \(L_i\) is the set of locations in the smart home \(h_i\) (e.g., living room, kitchen),
- \(P_H\) is the set of the state properties of the smart homes (e.g., cleanliness, temperature),
- \(P_Z\) is the set of the devices state properties (e.g., battery charge for a vacuum cleaning robot),
- \(H\) is the planning horizon of the problem. We denote with \(T = \{1, \ldots, H\}\) the set of time intervals,
- \(\theta : T \rightarrow \mathbb{R}^+\) represents the real-time pricing schema adopted by the energy utility company, which expresses the cost per kWh of energy consumed by consumers.

Finally, we use \(\Omega_p\) to denote the set of all possible states for state property \(p \in P_H \cup P_Z\) (e.g., all the different levels of cleanliness for the cleanliness property). Figure 1 shows an illustration of a neighborhood of smart homes with each home controlling a set of smart devices.

Figure 1: Illustration of a Neighborhood of Smart Homes

**Smart Devices**

For each home \(h_i \in H\), the set of smart devices \(Z_i\) is partitioned into a set of actuators \(A_i\) and a set of sensors \(S_i\). Actuators can affect the states of the home (e.g., heaters and ovens can affect the temperature in the home) and possibly their own states (e.g., vacuum cleaning robots drain their battery power when running). On the other hand, sensors monitor the states of the home.

Each device \(z \in Z_i\) of a home \(h_i\) is defined by a tuple \(\langle \ell_z, A_z, \gamma^H_z, \gamma^Z_z \rangle\), where \(\ell_z \in L_i\) denotes the relevant location in the home that it can act or sense, \(A_z\) is the set of actions that it can perform, \(\gamma^H_z : A_z \rightarrow 2^{P_H}\) maps the actions of the device to the relevant state properties of the home, and \(\gamma^Z_z : A_z \rightarrow 2^{P_Z}\) maps the actions of the device to its relevant state properties. We will use the following running example throughout this paper.

**Example 1** Consider a vacuum cleaning robot \(z_v\) with location \(\ell_{z_v} = \text{living\_room}\). The set of possible actions is \(A_{z_v} = \{\text{run, charge, stop}\}\) and the mappings are:

\[
\begin{align*}
\gamma^H_{z_v} : \text{run} &\rightarrow \{\text{cleanliness}\}; \quad \text{charge} \rightarrow \emptyset; \quad \text{stop} \rightarrow \emptyset \\
\gamma^Z_{z_v} : \text{run} &\rightarrow \{\text{battery\_charge}\}; \quad \text{charge} \rightarrow \{\text{battery\_charge}\}; \\
&\quad \text{stop} \rightarrow \emptyset
\end{align*}
\]

where \(\emptyset\) represents a null state property.

**Device Schedules**

We use \(\xi^t_{x} \in A_i\) to denote the action of device \(z\) at time step \(t\), and \(\xi_X^t = \{\xi^t_x \mid x \in X\}\) to denote the set of actions of the devices in \(X \subseteq Z\) at time step \(t\).

**Definition 1 (Schedule)** A schedule \(\xi^{t_a \rightarrow t_b}_X = (\xi^t_x^a, \ldots, \xi^t_x^b)\) is a sequence of actions for the devices in \(X \subseteq Z\) within the time interval from \(t_a\) to \(t_b\).

For example, the top row of Figure 2 shows a possible schedule \(\langle R, C, C, C, R, R, C, R \rangle\) for a vacuum cleaning robot starting at time 1400 hrs, where each time step is 30 minutes. The robot’s actions at each time step are shown in the colored boxes with letters in them: red with ‘S’ for stop, green with ‘R’ for run, and blue with ‘C’ for charge.

Figure 2: Smart Home Devices Scheduling Example
The high-level SHDS goal is to find schedules for all the devices in every smart home that achieve some user-defined objectives (e.g., the home is at a particular temperature within a time window, the home is at a certain cleanliness level by some deadline) that may be personalized for each home. We refer to these objectives as scheduling rules.

### Scheduling Rules

We define two types of scheduling rules: (i) Active scheduling rules (ASRs) that define user-defined objectives on a desired state of the home (e.g., living room is cleaned by 1800 hrs), and (ii) Passive scheduling rules (PSRs) that define implicit constraints on devices that must hold at all times (e.g., the battery charge on a vacuum cleaning robot is always between 0% and 100%). We introduce a simple syntax to express scheduling rules:

\[
\langle \text{location} \rangle \langle \text{state property} \rangle \langle \text{relation} \rangle \langle \text{state} \rangle \langle \text{time} \rangle^1
\]

**Example 2** The scheduling rule (1) describes an ASR defining a goal state where the living room floor is at least 75% clean (i.e., at least 75% of the floor is cleaned by a vacuum cleaning robot) by 1800 hrs:

\[
\text{living\_room\_cleanliness} \geq 75 \text{ before 1800 (1)}
\]

and scheduling rules (2) and (3) describe PSRs stating that the battery charge of the vacuum cleaning robot \( z_v \) needs to be between 0 and 100% of its full charge at all times:

\[
z_v \text{ battery\_charge} \geq 0 \text{ always (2)}
\]

\[
z_v \text{ battery\_charge} \leq 100 \text{ always (3)}
\]

For a home \( h_i \), we denote with \( R_p^{[t_a \rightarrow t_b]} \) a scheduling rule over a state property \( p \in P_H \cup \Phi \), and time interval \([t_a, t_b]\).

Each scheduling rule indicates a goal state (either a desired state of a home if it is an ASR or a required state of a device or a home if it is a PSR) at a location \( \ell_{R_p} \in L_i \cup Z_i \) of a particular state property \( p \) that must hold over the time interval \([t_a, t_b]\) \( \subseteq T \). Each rule is associated with a set of actuators \( \Phi_p \subseteq A_i \) that can be used to reach the goal state. Additionally, a rule is associated with a sensor \( s_p \in S_i \) capable of sensing the state property. Finally, in a PSRs the device can also sense its own internal states. More formally,

\[
\Phi_p = \{ z \in A_i | \ell_z = \ell_{R_p} \wedge \exists a \in A_z : p \in \gamma^H_z(a) \}
\]

\[
\Phi_p = \{ z \in A_i | z = \ell_{R_p} \vee \ell_z = \ell_{R_p} \wedge \exists a \in A_z : p \in \gamma^H_z(a) \}
\]

where the former defines ASR and the latter defines a PSR.

The ASR of Equation (1) is illustrated in Figure 2 by dotted red lines on the graph. The PSRs are not shown as they must hold for all time steps.

### Feasibility of Schedules

To ensure that a goal state can be achieved across the desired time window, the system has a predictive model of the various state properties.

---

1The type of relations that can be captured by our current implementation are: at \( t \), before \( t \), after \( t \), within \([t_1, t_2]\), and for \( t \) time units, with \( t, t_1, t_2 \in T \).
set of feasible state trajectories of that rule. Note that each active and passive scheduling rule defines a set of feasible state trajectories. For example, the active scheduling rule of Equation (1) allows all possible state trajectories as long as the state at time step 1800 is no smaller than 75. We use \( R_p[t] \subseteq \Omega_p \) to denote the set of states that are feasible according to rule \( R_p \) of state property \( p \) at time step \( t \).

More formally, a schedule \( \xi_{\phi_p}^{[t_a \rightarrow t_b]} \) satisfies a scheduling rule \( R_p^{[t_a \rightarrow t_b]} \) (written as \( \xi_{\phi_p}^{[t_a \rightarrow t_b]} \models R_p^{[t_a \rightarrow t_b]} \)) iff:

\[
\forall t \in [t_a, t_b] : \pi_p(\omega^t_p, \xi_{\phi_p}^{[t_a \rightarrow t_b]}) \in R_p[t]
\]

where \( \omega^t_p \) is the state of state property \( p \) at time step \( t_a \).

**Definition 4 (Feasible Schedule)** A schedule is feasible if it satisfies all the passive and active scheduling rules of each home in the SHDS problem.

The predicted state trajectories of the battery, charge, and cleanliness state properties following Equations (7) and (9) are shown in the second and third rows of Figure 2. These trajectories are predicted given that the vacuum cleaning robot will take on the schedule shown in the first row of the figure. The predicted trajectories of these state properties are also illustrated in the graph, where the dark grey line shows the states for the robot’s battery charge and the black line shows the states for the cleanliness of the room. The evaluated schedule is a feasible schedule, since the trajectories of both states over time satisfy both the active scheduling rule (1) and the passive scheduling rules (2) and (3).

**Cost of Schedules**

In addition to finding feasible schedules, the goal in the SHDS problem is to optimize for the aggregated total cost of energy consumed; we later define an egalitarian solution approach to this problem.

Each action \( a \in A_z \) of device \( z \in Z_i \) in home \( h_i \in H \) has an associated energy consumption \( \rho_z : A_z \rightarrow \mathbb{R}^+ \), expressed in kWh. The aggregated energy \( E^i_t(\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle) \) across all devices consumed by \( h_i \) at time step \( t \) under trajectory \( \xi_{Z_i}^{[0 \rightarrow T]} \) is:

\[
E^i_t(\xi_{Z_i}^{[0 \rightarrow T]}) = \sum_{z \in Z_i} \rho_z(\xi^t_z)
\]

where \( \xi^t_z \) is the action of device \( z \) at time \( t \) in the schedule \( \xi_{Z_i}^{[0 \rightarrow T]} \). The cost \( c_i(\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle \) associated to schedule \( \xi_{Z_i}^{[0 \rightarrow T]} \) in home \( h_i \) is:

\[
c_i(\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle) = \sum_{t \in T} (\ell^i_t + E^i_t(\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle)) \cdot \theta(t)
\]

where \( \ell^i_t \) is the home background load produced at time \( t \), which includes all non-schedulable devices (e.g., TV, refrigerator), and sensor devices, which are always active, and \( \theta(t) \) is the real-time price of energy per kWh at time \( t \).

**Optimization Objective**

The objective of an SHDS problem is that of minimizing the following weighted bi-objective function:

\[
\min_{\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle} \alpha_c \cdot C_{\text{sum}} + \alpha_e \cdot E_{\text{peak}}
\]

subject to:

\[
\forall h_i \in H, R_p^{[t_a \rightarrow t_b]} \in R_i : \xi_{\phi_p}^{[t_a \rightarrow t_b]} \models R_p^{[t_a \rightarrow t_b]}
\]

where \( \alpha_c, \alpha_e \in \mathbb{R} \) are weights, \( C_{\text{sum}} = \sum_{h_i \in H} c_i(\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle) \) is the aggregated monetary cost across all homes \( h_i \); and

\[
E_{\text{peak}} = \sum_{t \in T} \sum_{h_i \in H} (E^i_t(\xi_{Z_i}^{[0 \rightarrow T]} \mid x^i_{Z_i}^{[0 \rightarrow T]} \rangle))^2
\]

is a quadratic penalty function on the aggregated energy consumption across all homes \( h_i \). Finally, constraint (16) defines the valid trajectories for each scheduling rule \( r \in R_i \); where \( R_i \) is the set of all scheduling rules of home \( h_i \).

**Solution Approach**

We now describe our solution approach based on distributed constraint optimization problems (DCOP) (Modi et al. 2005; Petcu and Faltings 2005; Yeoh and Yokoo 2012; Fioretto, Pontelli, and Yeoh 2016). This is an egalitarian model, where agents are cooperative and seek to minimize the aggregated cost.

**Distributed Constraint Optimization Problems**

A distributed constraint optimization problem (DCOP) is a tuple \( \mathcal{P} = (\mathcal{X}, D, F, A, \alpha) \), where: \( \mathcal{X} = \{x_1, \ldots, x_n\} \) is a set of variables; \( D = \{D_1, \ldots, D_n\} \) is a set of finite domains (i.e., \( D_i \) is the domain of \( x_i \)); \( F = \{f_1, \ldots, f_e\} \) is a set of constraints (also called cost tables in this work), where \( f_i : \times_{x_j \in X_i} D_i \rightarrow \mathbb{R}^+ \cup \{\infty\} \) maps each combination of value assignments of the variables \( x^i \subseteq \mathcal{X} \) in the scope of the function to a non-negative cost; \( A = \{a_1, \ldots, a_p\} \) is a set of agents; and \( \alpha : \mathcal{X} \rightarrow A \) is a function that maps each variable to one agent.

A solution \( \sigma \) is a value assignment to a set of variables \( X_\sigma \subseteq \mathcal{X} \) that is consistent with the variables’ domains. The cost function \( F_{\mathcal{P}}(\sigma) = \sum_{f \in F, x \in X_\sigma} f(\sigma) \) is the sum of the costs of all the applicable constraints in \( \sigma \). A solution is said to be complete if \( X_\sigma = \mathcal{X} \) is the value assignment for all variables. The goal is to find an optimal complete solution \( x^* = \arg\min_{x^i} F_{\mathcal{P}}(x) \).

To describe the SHDS problem as a DCOP, it is required that agents control multiple variables (i.e., the set of actuators in each house). We thus use the Multiple-Variable Agents (MVA) formulation introduced in (Fioretto, Yeoh, and Pontelli 2016). One can map the SHDS problem to a DCOP as follows:

- **AGENTS:** Each agent \( a_i \in A \) in the DCOP is mapped to a home \( h_i \in H \).
VARIABLES and DOMAINS: Each agent \( a_i \) controls the following set of variables:

- For each actuator \( z \in A_i \) and each time step \( t \in T \), a variable \( x_{i,z,t} \), whose domain is the set of actions in \( A_z \). The sensors in \( S_i \) are considered to be always active, and thus not directly controlled by the agent.
- An auxiliary interface variable \( \tilde{z}_i^t \) whose domain is the set \( \{0, \ldots, \sum_{z \in Z_i} \rho(z(a)) \} \), which represents the aggregated energy consumed by all the devices in the home at each time step \( t \).

CONSTRAINTS: There are three types of constraints:

- **Local** soft constraints (i.e., constraints that involve only variables controlled by the agent) whose costs correspond to the weighted summation of monetary costs, as defined in Equation (14).
- **Local** hard constraints that enforce Constraint (16). Feasible schedules incur a cost of 0 while infeasible schedules incur a cost of \( \infty \).
- **Global** soft constraints (i.e., constraints that involve variables controlled by different agents) whose costs correspond to the peak energy consumption, as defined in the second term in Equation (15).

### Distributed Algorithm

SH-MGM is a distributed algorithm that operates in synchronous cycles. The algorithm first finds a feasible DCOP solution and then iteratively improves it, at each cycle, until convergence or time out. SH-MGM operates as follows:

- **FIRST CYCLE**: Each agent \( a_i \) starts up and independently searches for a solution \( \xi_{Z_i}^{[0-H]} \) to its local subproblem (i.e., schedule for all devices that satisfy all the rules of the home) that has the minimal cost \( c_i(\xi_{Z_i}^{[0-H]}) \). It then computes the energy consumption \( E_i^t(\xi_{Z_i}^{[0-H]}) \) of that schedule and broadcasts it to all the other agents in the problem.

- **SECOND CYCLE**: Each agent waits to receive the energy consumption of all the other agents. After receiving this information, it computes the peak energy consumption \( E^{\text{peak}} \) (second term in Equation (15)) of the problem with its current solution, and stores the weighted cost \( \alpha_e \cdot c_i(\xi_{Z_i}^{[0-H]}) + \alpha_e \cdot E^{\text{peak}} \) of its current solution.

Then, within a given time limit, it tries to find a new solution \( \tilde{\xi}_{Z_i}^{[0-H]} \) to its local subproblem that is no worse (i.e., whose weighted cost is no smaller) than its current solution. In other words,

\[
\alpha_e \cdot c_i(\tilde{\xi}_{Z_i}^{[0-H]}) + \alpha_e \cdot E^{\text{peak}} \leq \alpha_e \cdot c_i(\xi_{Z_i}^{[0-H]}) + \alpha_e \cdot E^{\text{peak}}
\]

where \( E^{\text{peak}} \) is the new difference in aggregated energy consumption that takes into account the new schedule of the agent.² If no time limit is imposed, it will find an optimal solution to its local subproblem. It then computes its gain \( G_i \) (improvement in cost):

\[
G_i = \left( \alpha_e \cdot c_i(\xi_{Z_i}^{[0-H]}) + \alpha_e \cdot E^{\text{peak}} \right) - \left( \alpha_e \cdot c_i(\tilde{\xi}_{Z_i}^{[0-H]}) + \alpha_e \cdot E^{\text{peak}} \right)
\]

between its current solution and new solution, and broadcasts this gain to all other agents in the problem. Upon receiving the gains of all agents, it checks if they are all 0, in which case the algorithm has converged to a local optima and no agent can unilaterally improve its schedule to improve the global solution (joint schedule of all agents). Otherwise, if the agent has the largest gain, then it will change its schedule to the new schedule. If it does not have the largest gain, it keeps its old schedule. Ties are broken using an order based on the agent IDs. This mechanism ensures that at most one agent will change its schedule at each time step, and that the new global solution will continuously improve until convergence. Finally, all the agents send the energy consumption of their respective schedules before starting the next cycle.

- The process repeats until convergence or a termination condition is satisfied (e.g., timeout, maximum number of cycles reached).

### Empirical Evaluations

**Hardware and Physical Implementation:** In order to evaluate SH-MGM in a realistic setting as possible, we implemented the algorithm on an actual distributed system of Raspberry Pis. A Raspberry Pi (called “PI” for short) is a bare-bones single-board computer with limited computation and storage capabilities. We used Raspberry Pi 2 Model Bs with quadcore 900MHz CPUs and 1GB of RAM. We implemented the SH-MGM algorithm using the Java Agent Development (JADE) framework,³ which provides agent abstractions and peer to peer agent communication based on the asynchronous message passing paradigm. Each PI implements the logic for one agent. The algorithm takes as inputs a list of simulated smart devices to schedule as well as their associated scheduling rules and the real-time pricing schema adopted. In order to find a feasible local schedules, the agent uses a Constraint Programming solver⁴ as subroutine. Finally, the agents communicate is supported through JADE, and using a wired network connected through a router.

---

²It is the sum of the energy consumption of the new agent’s schedule with that of the other agents’ schedules received at the start of the cycle.

³http://jade.tilab.com/

⁴We adopt the Java Constraint Programming (JaCoP) solver (http://www.jacop.eu/)
The Figure 3(left) shows an illustration of a PI with a Z-Wave dongle that can be used to issue commands to smart devices and receive information from them. Figure 3(right) shows a sample of smart devices that can be controlled. While our implementations can be used to schedule actual physical devices, we decided to use simulated devices as procuring a large number of commercially-available smart devices is too costly for the current project.

Experimental Setup: We set up our experiments with 7 Pis, each controlling 9 smart actuators—Tesla electric vehicle, Kenmore oven and dishwasher, GE clothes washer and dryer, iRobot vacuum cleaner, LG air conditioner, Bryant heat pump, and American water heater—to schedule, and 5 sensors. We selected these devices as they are available in a typical home and they have published statistics (e.g., energy consumption profiles). Each device has an associated active scheduling rule that is randomly generated for each agent and a number of passive rules that must always hold. The effect $\Delta_p$ of each device $p$ (see Equation (6)) on the different possible properties (e.g., how much a room can be cooled by an air-conditioner) is collated from the literature.

We set $H = 12$ and adopted a pricing schema used by the Pacific Gas & Electric Co. for its customers in parts of California, which accounts for 7 tiers ranging from $0.198$ per kWh to $0.849$ per kWh. Finally, we choose the weights $\alpha_c = \max \text{cost} / 0.5$ and $\alpha_e = \max \text{difference} / 0.5$ (see Equation (15)) so that both the components have equal normalized weights.

Experimental Results: To evaluate the impact of SH-MGM, we compared it against a baseline, where the agents schedule their devices in an uncoordinated way: Each agent finds a schedule that minimizes its local monetary cost and disregards the aggregated peak energy incurred. Figure 4 shows the results, where we imposed a timeout of 10 seconds for the CP solver. As expected, it shows that the SH-MGM solution improves with increasing number of cycles, providing economical advantage for the uses as well as peak energy reduction, when compared to the uncoordinated schema. These results, thus, show the feasibility of using a local search-based schema implemented on hardware with limited storage and processing power to solve a complex problem. The SH-MGM finds locally optimal DCOP solutions.

Conclusions and Future Work

With the proliferation of smart devices the automation of smart home scheduling can be a powerful tool for demand-side management within the smart grid vision. In this paper we proposed the Smart Home Device Scheduling (SHDS) problem, which formalizes the device scheduling and coordination problem across multiple smart homes as a multi-agent system. Furthermore, we describes a mapping of this problem to a distributed constraint optimization problem; This model is suitable in problems where agents are cooperative (e.g., buildings in a campus), while the latter is suitable in a setting where the agents are self-interested (e.g., homes in a neighborhood). We introduced a distributed local search algorithm to find locally optimal solutions, when formulated as a DCOP. This algorithm is implemented on an actual physical distributed system of Raspberry Pis, each capable of controlling and scheduling smart devices through hardware interfaces. Our experimental results shows that such approach outperforms a simple uncoordinated solution. Therefore, in this paper, we make the key first steps toward the formal modeling of the SHDS problem as well as deployment of distributed algorithms on physical systems.

In the future, we plan to tackle a number of significant challenges on multiple fronts including: (1) Investigating the use of more sophisticated algorithms that exploit the structure of the network to better propagate the problem constraints (e.g., as done in (Fioretto et al. 2014)), and conduct more comprehensive experiments; (2) Developing user-friendly user interfaces that will enable human users to interact with the system as well as provide scheduling rules; (3) Using machine learning techniques to automatically learn and predict such scheduling rules to improve the convenience factor of the users; and (4) Extending the SHDS model to allow conditional scheduling rules and to take into account uncertainty from background loads. These efforts, together with a number of others, are needed for actual deployment of such systems in the future.
