Monte-Carlo Tree Search for the Multiple Sequence Alignment Problem

Stefan Edelkamp and Zhihao Tang Bremen University {edelkamp,zhihao}@tzi.de

Abstract

The paper considers solving the multiple sequence alignment, a combinatorial challenge in computational biology, where several DNA RNA, or protein sequences are to be arranged for high similarity. The proposal applies randomized Monte-Carlo tree search with nested rollouts and is able to improve the solution quality over time. Instead of learning the position of the letters, the approach learns a policy for the position of the gaps. The Monte-Carlo beam search algorithm we have implemented has a low memory overhead and can be invoked with constructed or known initial solutions. Experiments in the BAliBASE benchmark show promising results in improving state-of-the-art alignments.

Introduction

Multiple sequence alignments (MSA) are frequently used for the analysis of DNA, RNA, or protein sequences in order to determine the evolutionary relation between species with a common ancestor, to predict the so-called secondary/tertiary structure, as well as the functional centers, in which as few possible mutations as possible occur (assuming that similar sequences inherit similar structures and function).

Computational biologists have declared the MSA problem to be a *holy grail* (Gusfield 1997). One reason is that solving this problem often leads to a high memory demands, which has been partially leveraged with frontier search (Hirschberg 1975; Korf et al. 2005), refined heuristics, and variants of memory-limited (Zhou and Hansen 2002; 2003) or iterativedeepening heuristic search (Schrödl 2005). Most of these approaches provide strategies to limit exploring the search space induced by dynamic programming (Bellman 1957). Tools like Clustal(W/Omega) and Blast compute approximate MSAs with probabilistic models.

Algorithmically, MSA boils down to the cost-optimal alignment of strings. Smaller problems can be solved optimally and the dynamic programming solution relates to approximate string matching. Precursor work in AI showed considerable scaling but often neglects biological relevant features like the inclusion of similarity cost matrices and affine gap costs. Exceptions are iterative deepening dynamic programming (Schrödl 2005), its externalization (Edelkamp and Kissmann 2007), and a search variant using partial expansion (Hatem and Ruml 2013). Still, the memory requirements raise exponentially with the problem complexity (measured in the sum of the input sequences).

In this paper we apply fixed-memory-bound randomized search that incorporates no expert knowledge in form of refined heuristics. The algorithm that we chose has successfully been used for vehicle routing (Cazenave 2012; Edelkamp and Gath 2014). It applies a series of random walks (rollouts) and learns a mapping (policy) for sampling the search space. It is able to improve over existing solutions and incorporates initial alignments into the search. As other algorithms are memory-bound, with its low memory profile it can serve as an add-on over existing approaches.

The paper is structured as follows. First, we provide a concise formulation of the MSA problem. Next, we consider the implementation of Monte-Carlo tree search that we have adapted to MSA optimization. Experimental results in the BAliBASE benchmark show advances to the state-of-the-art.

Problem Formulation

We start with some formal definitions.

Definition 1 (Sequence Alignment) Given a set of n sequences $S = \{s_1, s_2, \ldots, s_n\}$ with $s_i \in \Sigma^*$ for all $i = 1, 2, \ldots, n$, and Σ being a final alphabet. A sequence alignment (of length k) consists of a set of n sequences $A = \{a_1, a_2, \ldots, a_n\}$ with $a_i \in \Sigma'^*$ for all $i = 1, 2, \ldots, n$, where $\Sigma' = \Sigma \cup \{"-"\}$ and $"-" \notin \Sigma$. For each aligned sequence $a_i \in A$ we have length $|a_i| = k$. If all letters "-" are removed from $a_i \in A$, we get back s_i . For n = 2, the alignment is pairwise, for n > 2 multiple.

Definition 2 (Gap, Number, Length, Position) A gap G consists of a single or a sequence of letters g = "-".

Copyright © 2015, Association for the Advancement of Artificial Intelligence (www.aaai.org). All rights reserved.

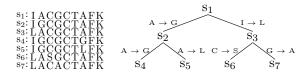

Figure 1: An MSA and its phylogenetic tree.

Moreover $gaps_num(a_i)$ is the number of empty letters in the aligned sequence $a_i \in A$ and |G| the length of gap G. Particularly we have |G| = 1 for $G = \langle g \rangle$ and letter g is located at position $gap_pos_i(g)$ in sequence $a_i \in A$.

For DNAs the alphabet Σ_{DNA} is {A, G, C, T} denoting the nucleo bases adenin, guanin, cytosin and thymin. For RNA the nucleo base uracil, abbreviated by U is used instead of thymin, so that $\Sigma_{RNA} = \{A, G, C, U\}$. The protein alphabet contains 20 amino acids.

In an alignment all sequences are written on top of each other such that the number of columns with matching letter is maximized. Gaps are inserted to slide letters in the alignment. A substitution occurs, if two different letters meet; a gap is a deletion and/or an insertion of a letter and called *indel*. The assumption is that the alignment with the least number of indels is biologically most plausible.

Fig. 1 shows an example of a protein MSA with n = 7 having no gaps, and the according phylogenetic tree where internal nodes denote the ancestor sequences, where I (Isoleucine), L (Leucine), F (Phenylalanine), K (Lysine) and S (Serine) are the one-letter abbreviations for the amino acids. To judge the quality of an MSA an evaluation function is required.

Definition 3 (Evaluation Function) An evaluation is a function $F : A \to \mathbb{R}$. For a pairwise alignment $A = \{a_1, a_2\}$ with $a_i = \langle c_{i1}c_{i2} \dots c_{ik} \rangle$ and $c_{ij} \in \Sigma'$, i = 1, 2and $j = 1, 2, \dots, k$, its evaluation is the sum of similarities f of all alignment columns $F(A) = F(a_1, a_2) = \sum_{j=1}^{k} f(c_{1j}, c_{2j})$. For a MSA $A = \{a_1, a_2, \dots, a_n\}$ the evaluation is the sum of values for all sequence pairs $F(A) = F(a_1, a_2, \dots, a_n) = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} F(a_i, a_j)$.

The evaluation function by (Levenshtein 1966) is used to compute *edit distances*. For DNA alignment we support scoring matrices used in WU-BLASTN (Altschul et al. 1990) and FASTA (Pearson 1994), and for protein alignment the PAM (Point Accepted Mutation) matrix (Dayhoff, Schwartz, and Orcutt 1978; Boeckenhauer and Bongartz 2010), the PET91 matrix (Jones, Taylor, and Thornton 1992), and BLOSUM (BLOck SUbstitution Matrix) (Henikoff and Henikoff 1992).

Definition 4 (Optimal MSA) Let \mathscr{A} be the set of all MSAs that can be generated by a set of sequences $S = \{s_1, s_2, \ldots, s_n\}$. The optimal MSA $A^* \in \mathscr{A}$ is an MSA with $F(A^*) = \min_{A \in \mathscr{A}} F(A)$, if the evaluation is based on distances or $F(A^*) = \max_{A \in \mathscr{A}} F(A)$.

Definition 5 (MSA Problem) Given a set of sequences $S = \{s_1, s_2, \ldots, s_n\}$, the MSA problem is to find the optimal MSA for A^* for S.

For a set of sequences more than one optimal MSAs may exist (Fig.2) yielding different biological explanations. All solutions have the same edit-distance 4. F(A) can calculate not only the similarities (maximum problems) but also the dissimilarities (minimum problems).

	-TC GTA	CACG AGAG	TCA- GTAC	-CG GAG	TCAC- GTAGA	₹G 4G	

Figure 2: Two sequences with 7 optimal MSAs.

We consider affine gap costs where gap opening has cost op and gap extension cost ex (per extension), so that gap G has total cost $P(G) = op + ex \cdot |G|$. Unfortunately, for biologists the values of op and ex in this refined cost model may vary (Hodgman, French, and Westhead 2010).

For a rising number of sequences the MSA problem is NPhard (Wang and Jiang 1994). For n sequences of maximal length q, standard dynamic programming (DP) computes an optimal solution with memory $O(q^n)$ and time $O(2^n \cdot q^n)$, so that alternative algorithms are required.

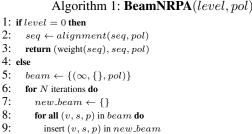

The algorithm iterative-deepening dynamic programming (IDDP) (Schrödl 2005) combines dynamic programming with iterative-deepening A* on the graph representation of the DP matrix. It expands edges not nodes. A lower bound h(e) is devised based on precomputed pattern database of triples. We have f(e) = g(e) + h(e), so that f(e) for an edge e is the estimated cost of a path of the start edge to reach the end edge via the current edge e IDDP inherits the advantages of DP and IDA*, it has a fixed ordering so that every node is visited once and includes a lower bound for guidance. A partial expansion alternative to IDDP has been proposed and parallelized by (Hatem and Ruml 2013).

Monte-Carlo Tree Search

Monte-Carlo search denotes a class of randomized tree search algorithms that has been designed for search spaces with large node branching factors and weak evaluation functions. By learning the proper choice of successors over time they can converge to the overall optimal solutions. In single-agent search, a series of optimization problems have been solved, e.g., TSPs with Time Windows (Rimmel, Teytaud, and Cazenave 2011; Cazenave and Teytaud 2012; Cazenave 2012) and Morpion Solitaire (Cazenave 2009; Rosin 2011).

Nested Monte-Carlo Search (NMCS) (Cazenave 2009) is a recursive algorithm that contributes to the fact that it is more important to erect the solution on the result of a recursive optimization process than looking at the next step only.

Nested Rollout Policy Adaptation (NRPA) (Rosin 2011) combines NMCS with policy learning. In NRPA we also apply nested search but a state-to-state policy is adapted. The branching being defined by an additional parameter called *iteration*. In every iteration a new random simulation (rollout) is conducted by sampling the policy. Improved solutions induce changes. In each level of the search an individual policy obtains a compromise between exploration and exploitation.

- 10: $temp_beam \gets \text{BeamNRPA}(level-1, p)$
- 11: for all (t_v, t_s, t_p) in temp_beam do
- 12: $t_p \leftarrow \operatorname{adapt}(p, t_s)$
- 13: insert (t_v, t_s, t_p) in new_beam
- 14: $beam \leftarrow \text{the } B \text{ best beams in } new_beam$
- 15: return beam

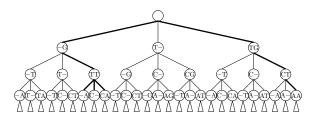

Figure 3: The search tree for a sample pairwise alignment.

Beam Nested Rollout Policy Adaptation (BeamN-RPA) (Cazenave 2012) is a variant of NRPA that maintains a policy for each solution, and a set of good solutions for each search level. The size of the set in level *i* is called *beam* and denoted by B_i . The pseudo-code is shown in Alg. 1. For each solution in a *level* BeamNRPA is called with level - 1. At the end B_{level} best solutions are generated return, so that the policies in higher search levels can be adapted. The adaptation of the policy is based on Bellmann updates and the same as in NRPA. The advantage of BeamNRPA is that it generalizes NRPA and naturally supports prior knowledge in form of solutions seeds.

MCTS for MSA

The intuitive method for the MSA problem is to enumerate possible alignments and after evaluating them, to choose the best one. The search tree can be constructed by a sequence of decisions and solved via NRPA and BeamNRPA. We study two possible encodings.

We assume that each letter v in Σ' has a fixed location index(v), so that for a string $V = \{v_1, v_2, \ldots, v_n\}$ in Σ'^* we obtain $index(V) = \sum_{i=1}^{n} index(v_i) \cdot |\Sigma'|^{n-i}$, where n is the length of V and $|\Sigma'|$ the size of the alphabet.

Construction of All Alignment Columns

An MSA consists of columns. Every column is a string in Σ'^n . In the search tree we generate, the root represents an empty node and all other nodes a column in the alignment. Thus, an MSA corresponds to a path from the root to the leaf (Fig. 3, optimal MSAs of Fig. 2 have bold edges).

Algorithm 2: alignment_col(alignment, policy)

1: $char_idx \leftarrow \{1, \ldots, 1\}$

- 2: $align_idx \leftarrow 1$
- 3: $col \leftarrow alignment.start$
- 4: repeat
- 5: $col.num \leftarrow enumeration(col.alternatives, char_idx, 0)$
- 6: sum = 0.0
- 7: for $i \leftarrow 1$ to col.num do
- 8: $value[i] \leftarrow \exp(policy[align_idx][col.alternatives[i]])$
- 9: $sum \leftarrow sum + value[i]$
- 10: $r \leftarrow \operatorname{rand}([0, \ldots, sum])$
- 11: $i \leftarrow 1$
- 12: $sum \leftarrow value[1]$
- 13: while $sum < r \operatorname{do}$
- 14: $i \leftarrow i + 1$
- 15: $sum \leftarrow sum + value[i]$
- 16: $col.index \leftarrow col.alternatives[i]$
- 17: transform the index col.alternatives[i] to the corresponding string
- 18: and save in col.string
- 19: for $i \leftarrow 1$ to n do
- 20: if col.string[i] is not a gap then
- 21: $char_idx[i] \leftarrow char_idx[i] + 1$
- 22: $align_idx \leftarrow align_idx + 1$
- 23: $col \leftarrow col.next$
- 24: until all sequences are read through

25: return alignment

During the construction the first step is to recursively enumerate all possible strings that may appear in this column (see Alg. 3). The depth of the tree is n as all strings have to have the same length. In each level for every letter of an alternative string s_i we have a) if all letters have been inserted then the following columns are labeled by a gap (line 6). b) if there are remaining letters that have a fit, then they are inserted to the MSA and the position i in this column either is the corresponding letter in s_i (lines 11–12) or a singletonletter gap (line 8). Additionally, the number of all alternative strings is returned. Temporary variables $char_i dx[i]$ store, how many letters have already been inserted to s_i .

In this model we learn, which string should appear in which column. The maximal length of an MSA is the sum of all input strings. A policy in this model is a mapping $\left(\sum_{i=1}^{n} |s_i|\right) \times |\Sigma'|^n$ where $|s_i|$ is the length of s_i .

A random MSA is constructed in Alg. 2. Exploiting the policy, a string is randomly chosen (lines 6-18). The variable $aliqn_i dx$ represents which column is currently constructed. With the variable and the index of an alternative string, we can access the policy value and determine the probability of choosing it. The last step is to update the variables to prepare for the next column (lines 19-23). The steps are repeated until all letters have been inserted, so that all columns are constructed and stored in a list. At the end, the MSA is evaluated and returned (line 25).

The enumeration process is recursive, starting with $seq_i dx = 0$ and ending with $seq_i dx = n$. As the transformation reads a string of length n, the worst case of Alg. 3 takes $T_{enum}(n) = 2 \cdot T_{enum}(n-1)$ steps with $T_{enum}(0) = O(n)$. This induces $T_{enum} = O(n \cdot 2^n)$. We see that the time for constructing a column is equal to

```
Algorithm 3: enumerate(A, char_idx, seq_idx)
```

1: if $seq_i dx = 1$ then

2: static $num \leftarrow 0$

```
3: static str \leftarrow \{0, 0, \dots, 0\}
```

- 4: if $seq_i dx \leq n$ then
- 5: if $char_idx[seq_idx] > |s_{seq_idx}|$ then
- 6: $str[seq_idx] \leftarrow$ the index of the gap character 7: enumerate(A, char_idx, seq_idx + 1)
- 7: enumerate(A, ch 8: else
- 9: $str[seq_idx] \leftarrow$ the index of the gap character
- 10: enumerate $(A, char_idx, seq_idx + 1)$
- 11: $str[seq_idx] \leftarrow$ the index of the $char_idx[seq_idx]$ -th
- 12: character in sequence s_{seq_idx}
- 13: enumerate(A, char_idx, seq_idx + 1)
- 14: else
- 15: $num \leftarrow num + 1$
- 16: transform the string str to the corresponding index
- 17: and save in a[num]
- 18: return num

Figure 4: Resolving gap-only columns.

 $\begin{array}{l} T_{col}=T_{enum}+2\cdot O(2^n)+2\cdot O(n)+O(1)=O(n\cdot 2^n).\\ \text{Moreover, as we use the sum-of-pairs evaluation we get}\\ T_{eval}\ =\ C_n^2\cdot k\ =\ O(k\cdot n^2), \text{ where }k \text{ is the length}\\ \text{of the sequence alignment. Together we have }T_{colalign}\ =\ k\cdot T_{col}+T_{eval}\ =\ O(k\cdot n\cdot 2^n+k\cdot n^2)\ =\ O(q\cdot n^2\cdot 2^n),\\ \text{with }k\ =\ n\cdot q \text{ being the worst case, and }q \text{ being the maximal length of all sequences.} \end{array}$

Construction of All Alignment Gaps

Def. 1 implies that a sequence alignment is fully determined by the position of gaps. Based on this state representation idea for each sequence s_i the policy is stored as a matrix of size $gap(a_i) \cdot k$, where $gap(a_i)$ is the number of gap letters in the aligned sequence a_i and k the length of the alignment. Again, Monte-Carlo tree search is used to learn, where a gap letter is present in which column of the alignment.

If the length of the alignment is known the number of gap letters can be determined upfront (line 2). Then the positions of all gaps letters can be chosen one after the other (lines 5– 17). The temporary variable is_gap helps to determine all legal gap positions (lines 3, 6–11 and 19). The algorithm is executed for all sequences until the entire MSA can be evaluated (line 21). After all gaps in one sequence are done, we can sort them (line 20) which has pros and cons.

We avoid gap-only columns by moving the gap in the longest sequence to $gap_pos_{new} = (gap_pos_{org} + (-1)^i \cdot \lfloor (i+1)/2 \rfloor) \mod k, i = 1, 2, 3, \ldots$ (see Fig. 4). We check that there are no gap-only columns left. If no satisfying position can be found, the original one is maintained. Alg. 4 does, however, not cover this special case. Alternatively, we may allow gap columns, as they do not change the score.

The running time of this model is easy to analyze. A

Algorithm 4: alignment_gap(alignment, policy)

```
1: for seq_i dx \leftarrow 1 to n do
```

- $2: \quad alignment.gaps_num[seq_idx] \leftarrow$
- $alignment.length |s_{seq.idx}|$
- 3: $alignment.is_gap[seq_idx] \leftarrow \{FALSE, \dots, FALSE\}$
- 4: for $gap_idx \leftarrow 1$ to $alignment.gaps_num[seq_idx]$ do
- 5: $sum \leftarrow 0.0$
- 6: for $pos \leftarrow 1$ to alignment.length do
- 7: if $\neg alignment.is_gap[seq_idx][pos]$ then
- 8: $value[pos] \leftarrow \exp(policy[seq_idx][gap_idx][pos])$
- 9: $sum \leftarrow sum + value[pos]$
- 10: else
- 11: $value[pos] \leftarrow 0.0$
- 12: $r \leftarrow \operatorname{rand}([0, \ldots, sum])$
- 13: $pos \leftarrow 1$
- 14: $sum \leftarrow value[1]$
- 15: while $sum < r \operatorname{do}$
- 16: $pos \leftarrow pos + 1$
- 17: $sum \leftarrow sum + value[pos]$
- 18: $alignment.gaps_pos[seq_idx][gap_idx] \leftarrow pos$
- 19: $alignment.is_gap[seq_idx][pos] \leftarrow TRUE$
- 20: /* sort alignment.gaps_pos[seq_idx] or not */
- $21: \ \textbf{return} \ alignment$
 - $\begin{array}{ccc} \mathrm{A-CGG} \\ \mathrm{A--TG} \\ \mathrm{ATCGG} \\ \mathrm{ATCGG} \\ \mathrm{A-TG} \\ \mathrm{ATCGG} \end{array} \begin{array}{c} \mathrm{A--TG} \\ \mathrm{ATCGG} \end{array}$

random alignment is constructed one by one. Sequence s_i contains $k - |s_i|$ gap letters. We obtain $T_{gapalign} = O(\sum_{i=1}^n \sum_{j=1}^{k-|s_i|} (2k)) + T_{eval} = O(q^2 \cdot n^3)$, with $k = n \cdot q$ in the worst case and q being the maximal sequence length.

Construction of an Initial Alignment

In the second model, prior knowledge is requested in the form of the length of the optimized alignment. This information can be supplied by the user or via an initial alignment. This section provides an algorithm to construct an initial alignment automatically (Kurtz 2007).

Definition 6 (Projection) Let $S = \{s_1, \ldots, s_n\}$ be a set of sequences and S' a subset of S. Assume $A_S = \{a_1, \ldots, a_n\}$ to be an MSA of S. The projection of A_S wrt. S' is the MSA $proj(A_S, S')$, constructed as follows

- all rows in A_S that do not correspond to sequences in S' are removed
- all columns that only contain gap letters are removed.

If $A_{S'} = proj(A_S, S')$, where $A_{S'}$ is an MSA of S', we say that A_S is compatible with $A_{S'}$.

An example for $S = \{\text{``ACGG'', ``ATG'', ``ATCGG''}\}$, $S' = \{\text{``ACGG'', ``ATG''}\}$ and $S'' = \{\text{``ATG'', ``ACTCGG''}\}$ is shown in Fig. 5. We see an MSA A_S of S, a projection $proj(A_S, S')$, and another projection $proj(A_S, S'')$.

Definition 7 (Alignment Tree) An alignment tree for a set of sequences S is a labeled tree. In this tree the node set is S and every edge (i, j) is labeled by the optimal pairwise alignment of two sequences s_i and s_j .

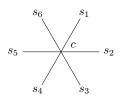

Figure 6: A star alignment tree of sequences $\{c, s_1, \ldots, s_6\}$.

Algorithm 5: initial_alignment()

```
1: for i \leftarrow 1 to n do
2: for j \leftarrow i + 1 to n do
3:
         compute the optimal alignment of s_i and s_j with distance d_*(s_i, s_j).
4: for i \leftarrow 1 to n do
5: total[i] \leftarrow 0
6:
      for i \leftarrow 1 to n do
7:
          total[i] \leftarrow total[i] + d_*(s_i, s_j)
8: c \leftarrow \arg\min_i total[i]
9: choose an arbitrary sequence s \in S \setminus \{s_c\}
10: let A be the optimal pairwise alignment of s_c and s
11: S' \leftarrow \{s_c, s\}
12: while S' \neq S do
13: choose an arbitrary sequence s \in S \setminus S'
14:
       combine A with the optimal pairwise alignment of s_c and s
15:
       S' \leftarrow S' \cup \{s\}
16: return A
```

In an alignment tree the relation between all sequence pairs are represented. There are different options for constructing such tree. We consider the special case of the tree being star-shaped (Fig. 6).

The algorithm for constructing an initial MSA has two stages. The basis is a set of precomputed pairwise alignments (see Alg. 5). For each pair of sequences (s_i, s_j) the distance to the optimal alignment is computed (lines 1–5). For each sequence s_i all distances of the optimal alignment corresponding to s_i are added (lines 6–11). The sequence with the minimal total distance is chosen as the center (line 12), all other sequences are leaves.

The second stage is to construct an MSA based on the pairwise alignment stored at the edges. Whenever an MSA of the sequences $\{c, s_1, \ldots, s_i\}$ is constructed, the optimal pairwise alignment of c and s_{i+1} is inserted. This insertion preserves the rule *once a gap always a gap*. Therefore, the constructed MSA is compatible with all pairwise alignments in the alignment tree. For example, c = "ATGCATT", $s_1 = \text{"AGTCAAT"}$ and $s_2 = \text{"ACTGTAATT"}$. The alignments of c and s_1 or c and s_2 are

$$a = ATG-CATT$$
 $a' = A-TGC-ATT$
 $a_1 = A-GTCAAT$ and $a'_2 = ACTGTAATT$

In the second alignment we find a gap prior to letter 'T' in d sequence a'. According to the golden rule the gap in a'' is preserved. Through the combination from a and a' we can generate a'' = "A-TG-C-ATT", so that the final MSA is

The MSA is not optimal as we could substitute a_2'' by "ACTGT–AATT". It is, however, a good approximation.

Definition 8 (Proper Cost Function) *A similarity*

a''=A-TG-C-ATT $a''_1=A--GTC-AAT$ $a''_2=ACTG-TAATT$

cost function f is proper if 1) for all $x \in \Sigma'$, we have f(x,x) = 0; 2) for all $x, y, z \in \Sigma'$, we have $f(x,z) \leq f(x,y) + f(y,z)$.

Lemma 1 Assume a proper similarity cost function f, and d being the column sum of f, a set of sequences $S = \{c, s_1, \ldots, s_n\}$ and a star alignment tree T with center c. If $A = \{a, a_1, \ldots, a_n\}$ is an MSA of S with length k that is compatible with all optimal alignments in T, then for all $1 \le i, j \le n$ we have $F(a_i, a_j) \le F(a_i, a) + F(a, a_j) = F_*(s_i, c) + F_*(c, s_j)$.

Proof: We consider column r in MSA A. According to the second property of a proper cost function for an arbitrary letter $b \in \Sigma'$ we have $f(a_i[r], a_j[r]) \leq f(a_i[r], b) + f(b, a_j[r])$. If b = a[r], we have $f(a_i[r], a_j[r]) \leq f(a_i[r], a[r]) + f(a[r], a_j[r])$. The distance of a pairwise alignment is the sum of distances of all columns. Thus,

$$F(a_i, a_j) = \sum_{r=1}^{k} f(a_i[r], a_j[r])$$

$$\leq \sum_{r=1}^{k} \left(f(a_i[r], a[r]) + f(a[r], a_j[r]) \right)$$

$$= \sum_{r=1}^{k} f(a_i[r], a[r]) + \sum_{r=1}^{k} f(a[r], a_j[r])$$

$$= F(a_i, a) + F(a, a_j).$$

Following the assumption we have that the MSA A is compatible with all optimal alignments in T. Therefore, the projections of A wrt. $\{s_i, c\}$ are optimal alignments of s_i and c. Folling the first property of a proper cost function, we have f(-, -) = 0, so that the distance of a pairwise sequence alignment does not change if an only-gap column is removed. Hence, $F(a_i, a) = F_*(s_i, c)$, and $F(a, a_j) = F_*(c, s_j)$. \Box

Theorem 1 Let $S = \{s_1, \ldots, s_n\}$ be a set of sequences, f be a proper similarity cost function, F be the column sum of f, and $A = \{a_1, \ldots, a_n\}$ be an MSA of S, constructed via Alg. 5. Then, $F(a_1, \ldots, a_n) \leq (2 - \frac{2}{n}) \cdot F_*(s_1, \ldots, s_n)$.

Proof: We assume that MSA $A^* = \{a_1^*, \ldots, a_n^*\}$ is optimal for *S*, i.e., $F(a_1^*, \ldots, a_n^*) = F_*(s_1, \ldots, s_n)$, and $c = s_n$ is the center. We compute the distance between *A* and A^* .

$$F(a_1, \dots, a_n) = \sum_{i=1}^{n-1} \sum_{j=i+1}^n F(a_i, a_j) = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n F(a_i, a_j)$$

$$\leq \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \left(F_*(s_i, c) + F_*(c, s_j) \right)$$

$$= \frac{1}{2} \left(\sum_{i=1}^{n-1} \sum_{j=1}^{n-1} F_*(s_i, c) + \sum_{i=1}^{n-1} \sum_{j=1}^{n-1} F_*(s_j, c) \right)$$

$$= \frac{1}{2} \left(\sum_{j=1}^{n-1} \sum_{i=1}^{n-1} F_*(s_i, c) + \sum_{j=1}^{n-1} \sum_{i=1}^{n-1} F_*(s_i, c) \right)$$

$$= (n-1) \cdot \sum_{i=1}^{n-1} F_*(s_i, c)$$

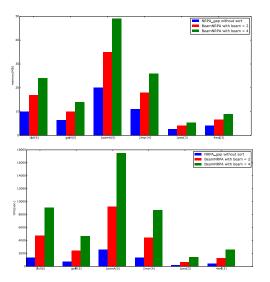

Figure 7: Space (top) and time needed by (Beam)NRPA.

and

$$F(a_1^*, \dots, a_n^*) = \sum_{i=1}^{n-1} \sum_{j=i+1}^n F(a_i^*, a_j^*)$$

= $\frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n F(a_i^*, a_j^*)$
 $\ge \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n F_*(s_i, s_j)$
= $\frac{1}{2} \sum_{i=1}^n \left(\sum_{j=1}^n F_*(s_i, s_j) \right)$
 $\ge \frac{1}{2} \sum_{i=1}^n \left(\sum_{j=1}^n F_*(c, s_j) \right)$
= $\frac{1}{2} n \cdot \sum_{j=1}^n F_*(c, s_j) = \frac{1}{2} n \cdot \sum_{i=1}^n F_*(s_i, c)$

Therefore, we have

$$\frac{F(a_1, \dots, a_n)}{F_*(s_1, \dots, s_n)} = \frac{F(a_1, \dots, a_n)}{F(a_1^*, \dots, a_n^*)}$$
$$= \frac{(n-1) \cdot \sum_{i=1}^{n-1} F_*(s_i, c)}{\frac{1}{2}n \cdot \sum_{i=1}^n F_*(s_i, c)} = 2 - \frac{2}{n}. \square$$

The MSA that is constructed via the star-shaped alignment tree is, therefore, an upper bound for the distance of the optimal MSA (Kurtz 2007).

Experimental Results

Experiments were ran on a Debian v7.8 32 GB RAM PC (using 1 of the AMD FX(tm)-8350's 4,0/4,2GHz 8-cores), taking GNU's g++ (v4.7.2, -O3). For scoring, PAM250 and affine gap cost wrt. -10x - 1 for gap length x were used.

We took the BAliBASE benchmark (ftp://bess.ustrasbg.fr/pub/BAliBASE2), which has been designed to compare the efficiency of different MSA algorithms¹. BAliBASE is a library of biologically alignments that optimize an informal biological *meaning*. Having a formal sum of pairwise scores on BAliBASE entries cannot replace a comparison with bioinformatics competitors such as Clustal-Omega (Clu 2011), MUSCLE (Edgar 2004a; 2004b) or MAFFT (Katoh 2013). However, our interest was showing the potential of MCTS for the MSA problem in terms of saving space and posthoc optimization during the search. Originally, we wanted to compare our algorithm with Genetic Algorithms (e.g., the program SAGA). But we did not do it, due to the non-optimal results for the search without the initial alignment.

Reference 1 consists of 82 sequence groups, partitioned into 9 classes according to the length (short, medium, long) and similarity (large, medium, small). Among those we chose *test 3*, consisting of 28 sequence groups with three to six sequences of different similarity. From the set of MSAs we chose 1ped and 4enl (3 sequences) and 1lcf (6 sequences), together with the groups 2myr (4), ga14 (5), and 1pamA (4), which are supposedly the hardest (Hatem and Ruml 2013; Schrödl 2005). The implementation supports FASTA and MSF formats. The web presentation comes with manual close-to-optimal solutions.

For these sequence groups at most 20MB RAM was allocated, which is by far lower than the one in IDDP and variants. On the other hand, BeamNRPA was better than NRPA: the wider the beam, the better the solution. The number of rollouts for BeamNRPA its $beam \cdot iteration^{level}$ (we allow a beam width other than 1 only in level 1), and chose beam = 1, 2, 4, iteration = 50 and level = 3. BeamNRPA with beam = 1 is NRPA. The initial alignment is defined by the star algorithm and improved by the optimizer.

In NRPA_col a policy is a matrix of size $(\sum_{i=1}^{n} |s_i|) \times |\Sigma'|^n$, so that the memory requirements are exponential in n. This leads NRPA_col to fail for 5-6 sequences and to bad results in many others.

For NRPA_gap a policy is a matrix of size $(k - |s_i|) \times k$ for every s_i , so that memory requirements are polynomial in $|s_i|$ and k. Only 4 of 28 groups needed more than 10MB space, and 20MB was the overall maximum. For DP and its variants the space complexity is $O(|s_1| \cdot \ldots \cdot |s_n|)$. A biological sequence (DNA/protein) may have over one thousand bases/amino acids. Hence, the memory requirements are huge. Our algorithm saves only the positions of all gaps in an alignment. Obviously, the number of gaps is much less than the length of an aligned sequence. Therefore, the required memory in our program is very small.

Sample learning curves for 1ped and 1pamA are shown in Fig. 8 and Fig. 9), respectively. NRPA_gap without sorting often resulted in a better quality than with sorting, where *lpamA*, *2myr* and *llcf* are the only exceptions (see Table 1). Thus, we used no sorting in BeamNRPA. Memory and time performances of NRPA and BeamNRPA are cross-compared

¹BAliBASE3 (http://www.ncbi.nlm.nih.gov/pubmed/ 16044462) is considered by specialists as a bad benchmarking resource even for identifying good scoring functions. Moreover, BAliBASE version 2 is used in all precursing AI publications.

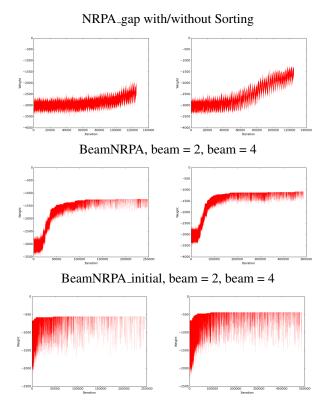

Figure 8: Learning curves of *1ped*.

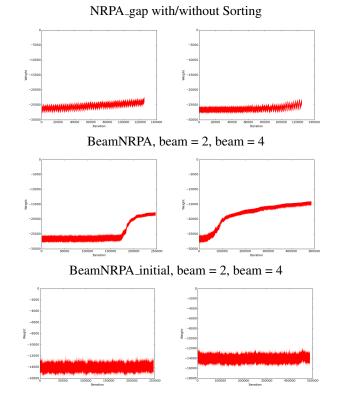

Figure 9: Learning curves of *1pamA*.

in Fig. 7 and listed in Table 1 and 2. The wider the beam, the higher the computational cost. On the other hand, as shown in Fig. 8, the larger the search tree, the better the solution found by BeamNRPA.

Next, we tested whether an initial alignment could be improved (see Table 3). After determining the alignment, we called the adaptation function 10 time (α -value of 1) to come up with an initial policy. For the sequence group *1ped* an alignment better than the initial one was found quickly (see Fig. 8). The initial alignment of *1pamA* had a score of -8291. Unfortunately, for this hardest group BeamNRPA did not improve much within the given parameter range (see Fig. 9).

Finally, we optimize best-known solutions from the BAliBASE benchmark with BeamNRPA_gap. Table 4 shows an improvement (wrt. our cost function) in 20 groups, equal results in 6 groups (1ac5, 1bgl, 1dlc, 1fieA, 1gpb, 1gtr) and worse result in 2 groups (1pamA and 1taq).

Altogether there are 28 sequence groups. For the groups 1pamA and 1taq our program cannot return a better solution than BAliBASE (from beam = 2 and 4). For these 6 groups (1ac5, 1bgl, 1dlc, 1fieA, 1gpd and 1gtr) our program returns the same good solutions as BAliBASE (from beam = 2 and 4). For the other 20 groups the better solutions are found from beam = 2 or 4 (beam = 2 sometimes can return a better solution than beam = 4).

Conclusion and Outlook

In this paper we pioneered Monte-Carlo tree search for the multiple sequence problem. The results for learning gaps with BeamNPRA are very promising. The approach has a very low memory overhead, can be used from scratch and for post-hoc optimization, Wrt. our cost function we found improvements to many published BAliBASE alignments.

It is possible to improve the policy representation by learning inter-dependencies of gap positions within the set of sequences. A further yet unexplored option is the parallelization of BeamNRPA. In (Rosin 2011) it has been said that parallelizing NRPA is involved, since the policy has to be shared among the threads. The advantage of BeamNRPA is that it is easier to parallelize as all policies in the beam can be read and updated concurrently. It has the additional feature that it can be parallized in every level of the search. As the number of iterations is usually larger than the number of threads, the searches in each thread are iterative. Another option to deal with concurrency issues in the parallelization is to use low-level compare-and-swap.
